Keywords: Spatial OLAP, incomplete continuous field, multi-resolution geographic data

Abstract: Integrating continuous spatial data into SOLAP systems is a new research challenge. Moreover, representation of field data at different scales or resolutions is often mandatory for an effective analysis. Thus, in this paper, we propose a logical model to integrate spatial dimensions representing incomplete field data at different resolutions in a classical SOLAP architecture.

1 INTRODUCTION

Spatial Data Warehouse (SDW) and Spatial OLAP (SOLAP) systems play an important role in helping decision-makers obtain the maximum benefits of these large amounts of geographic data (Bédard, Merrett et al. 2001). These technologies extend Data Warehouse (DW) and OLAP systems to integrate spatial data with warehoused classical data to achieve the on-line analysis of large georeferenced data sets. SOLAP systems integrate advanced OLAP and Geographic Information Systems (GIS) in a unique framework usually based on the relational storage (i.e. Oracle, etc.) of spatial data according to the vector model, and their analysis through SOLAP operators (Spatial Roll-Up, Spatial Slice, etc.) implemented by the SOLAP server (e.g. Map4Decision, etc.) and visualized by means of tabular, graphical and cartographic displays (Gomez, Gomez et al. 2012). SDW are modeled according to the spatio-multidimensional model that extends the traditional multidimensional model to define spatial dimensions (i.e. analysis axes with spatial attributes) and spatial measures (i.e. analysis subjects) that integrate geographic information using the vector model (Bédard, Rivest et al. 2007). SOLAP technology can be applied in different domains (e.g. archeology, public health, etc.).

Geographic information can be represented by discrete (vector) and continuous field (Mennis, Viger et al. 2005). Continuous fields (also called continuous spatial data) represent physical phenomena that continuously change in space (Paolino, Sebillo et al. 2010), for example the temperature, population, etc. Two representations of field data have been proposed: incomplete and complete (Paolino, Sebillo et al. 2010). Incomplete representations store a sample of points and need additional functions to calculate the field in non-sampled areas (e.g. grid of points, TIN, etc.) (e.g. Figure 2). Complete representations associate estimated values to regions and assume that these values are valid for each point in the regions (e.g. raster). For those representations some ad-hoc analysis operators have been defined that allow a point by point analysis (i.e. map algebra (Mennis, Viger et al. 2005)). Representation of geographic data at different scales or resolutions (e.g. Figure 2-b) is mandatory for an effective analysis of spatial complex phenomena since it represents a geovisualization method (Camossi, Bertino et al. 2009). Consequently, these resolutions or scales represent decision-makers analysis needs that should be explicitly represented in any data and query model. Indeed, in the context of Geographic Information Systems and Spatial Databases Management Systems (SDBSM), several works addresses this issue by proposing conceptual, logical and physical data models and analysis techniques (Parent, spaccapietra et al. 2006).

Motivated by the important analysis capabilities offered by the continuous field representation of geographic data when integrated in SOLAP systems
behind the building) (Figure 2-c). It is also possible
interested in the odor value at 10:00 in the area
the spatial dimension (for example, s/he should be
ask for the result of any OLAP query in any point o f
continuous way, decision-makers should be able to
2-a).

different resolutions, we propose in this paper: (i) a
analysis of incomplete regular grid field data at
and (iii) a continuous view of the field.

In order to show our proposal, we present a case
study based on data issued from the monitoring of
urban odor. For each 15 minutes and type of odor
(e.g. NO2) a regular grid map (field) is produced by
means of some sample points and a simulation
model (ADMS5). The simulation model estimates
odors for a whole urban area and produces 100*100
grid points closest to the unknown point and calculates a
distance weighted average which determines in what
proportion the value of a neighbour impact on the
value of the point to be estimated (Figure 1).

Finally, as stated in the previous section, since
visualization of spatial data at different resolutions is
mandatory for the exploration/analysis process,
decision-makers should be able querying spatial
warehoused data at different resolutions. It is very
important to note that for each spatial phenomenon a
set of useful known resolutions exist, so they could
be predefined according to data and users needs.
Moreover, in order to calculate values at finer
resolutions spatial interpolation functions as previously
described can be used.

To summarize, spatio-multidimensional analysis
of field data implies: supporting (i) OLAP classical
operators as Map Algebra, (ii) continuous view of
spatial data, (iii) spatial slice operators using field
data, and (iv) visualizing and querying data at
different predefined resolutions.

2 MODELING AND ANALYSIS
REQUIREMENTS

In order to show our proposal, we present a case
study based on data issued from the monitoring of
urban odor. For each 15 minutes and type of odor
(e.g. NO2) a regular grid map (field) is produced by
means of some sample points and a simulation
model (ADMS5). The simulation model estimates
odors for a whole urban area and produces 100*100
grid points closest to the unknown point and calculates a
distance weighted average which determines in what
proportion the value of a neighbour impact on the
value of the point to be estimated (Figure 1).

Moreover, in order to calculate values at finer
resolutions spatial interpolation functions as previously
described can be used.

To summarize, spatio-multidimensional analysis
of field data implies: supporting (i) OLAP classical
operators as Map Algebra, (ii) continuous view of
spatial data, (iii) spatial slice operators using field
data, and (iv) visualizing and querying data at
different predefined resolutions.

3 Spatio-multidimensional model
for incomplete field data

In this section we describe our spatio-
multidimensional model for handling incomplete
fields at different resolutions. Our model extends the
classical spatio-multidimensional models to generate
the continuity of the phenomena over the studied
area, and represents pre-defined levels of resolution.
In particular, a “Cube” is composed of “Facts” and
“Dimensions”. A “Dimension” is composed of
“Hierarchies”, which are composed of “Levels”. A
“Level” can be spatial or conventional. This means
that it can contain “Spatial attributes” (e.g. points,
etc.), or contain only alphanumerical attributes
respectively. “Facts” is composed of “Spatial
Measures” or “Conventional Measures”. Moreover,
our extension defines a “Field level” as a special
type of spatial level where each member has a
geometric attribute (e.g. point), a “neighbourhood
relationship" association, and a resolution level to which it belongs.

![Image](image_url)

Figure 2: a) local map algebra aggregation over incomplete field. b) multiresolution representation over incomplete field c) querying an unsampled point d) querying an unsampled zone

Indeed, as described in the previous section a spatial interpolation function uses a set of points, which depend on the function (e.g. bilinear function uses a 2x2 grid), to estimate the unknown value. Thus, in our approach values are represented by measures, the “Neighbourhood relation” links each detailed "Field level" to its neighbours in the less detailed level. As soon as the value of a high resolution "Field level" is required its neighbours are found through the “Neighbourhood relation”. However, this type of relationship can be implemented in different ways, depending on the intended purpose as shown in the next section. In our case, we want to estimate the value of any point (x, y) of a Field level, so neighbours are found on the fly by the relation "Neighbourhood relation". In the case of a change in the level of resolution, the members of a high resolution (e.g. 200x200), are predefined and therefore, their respective neighbours, which belongs to the resolution 100x100, can be pre-stored as attributes.

As described in the model, a hierarchy can contain several field levels representing the phenomena at different resolutions. This means that changing resolutions implies navigating into the hierarchy and calculating values by means of the interpolation function or an ad-hoc aggregation function when we move from less detailed resolution to more detailed one, or vice versa.

The odor SDW of our case study using our spatio-multidimensional model is shown in Figure 3. This instance describes the dimensions and facts that constitute our cube.

In addition to the dimensions (Source, Tracer and Time), the "Facts" class has a classical measure "odorMeasure" and a derived measure "EstimatedOdorMeasure". The derived measure is calculated according to two functions:
a)"Interpolatepoint"(continuity), b)"InterpolateBilinear" (multiresolution). In our case, the interpolation function used is the "bilinear interpolation". The relationship whose cardinalities are "2, 4" represents the “Neighbourhood relation”. A member of the "Incomplete Field Level" can have 2 or 4 neighbours, depending on its position in the grid 2x2 that surrounds it. The “Neighbourhood relation” can be used to retrieve neighbours of a location (x,y) to estimate the value in that position (continuity), or to retrieve a high resolution member’s neighbours in the lower level of resolution to estimate its value (multiresolution on the fly).

4 Relational and OLAP models

In this section we present the implementation of our spatio-multidimensional model in a typical relational SOLAP architecture based on SQL (the Relational DBMS standard language) and MDX, which is the de-facto standard of OLAP Servers. This provides a generality character to our approach, being possible to be implemented in any architecture of this kind.

Let us suppose to have one “Field level” representing points at the resolution 100x100, and then the logical model of our case study is represented as in fig. 4. It is a classical star schema. This model is composed of a fact table containing measures with foreign keys to dimension tables. Each dimension table is denormalized, and has attributes representing levels.

Let us also suppose to have a classical OLAP model based on that logical schema, where the spatial level is called [Field].[res100]. As we can see, the dimensions that constitute the model are: the temporal dimension, which consists of five levels of granularity (Year, month, day, hour and minute); the Source dimension that expresses the source of the pollutant (e.g. cars); the Tracer dimension is the type of pollutant (eg NO2), which is also defined by its identifier and name; and the “Field dimension” that represent a regular grid of points and consists of one level representing the regular grid at the 100x100 resolution, which is
composed of an identifier and a geometry representing a point. The measure «Concentration of odor» represents the values for all members representing the field at a 100*100 resolution. This representation of incomplete field data in the multidimensional model allows making queries as Map Algebra operators (point by point aggregation) such as the following:

**Query 1:** select average odor for each field member during 2012

```sql
SELECT [Field].[res100]. Members ON ROWS, [{time}.[2012]] ON COLUMNS FROM [odorCube] WHERE [Measures].[value]
```

4.1 Incomplete field

In order to implement field levels we have defined a GeoMDX user-defined function that represents a spatial interpolation as:

```
NumcericType InterpolatePoint(Geometry)
```

This function takes as input a geometry (point) and returns a numerical value, which is a derived measure in the OLAP model, representing an estimated value calculated using the neighbourhood values of the point given in input. Thus, let us suppose that we want to retrieve a value of the field in a location whose geometric property is set to the geometric coordinates POINT(-72.1235 42.3521). Then in order to answer to that need using the Bilinear interpolation function, decision-makers have to simply use a GeoMDX function in the following way: `InterpolatePoint(POINT(-72.1235 42.3521)).`

Thus, the function will look for the neighbours of the point given as a parameter, in the field level ([Field].[res100]), on the basis of the distance, and then find neighbours’ respective values in the fact table, evaluate the value of the point to estimate using these values, and then return an estimated derived measure. Here is an example query that uses the "InterpolatePoint" function:

**Query 2:** select a field member’s value at coordinates (721148 3140020) for the year 2012.

With member [Measures].[value] as 'InterpolatePoint(ST_GeomFromText("POINT (721148 3140020)")))'

```sql
SELECT [Measures].[value] ON ROWS, [{time}.[2012]] ON COLUMNS FROM [odorCube]
```

Note that generally MDX allows defining user-defined functions in several programming languages (i.e. Java, .NET, etc.) depending of the OLAP Server used. In this work we have used a Java-based
implementation in GeoMondrian (see Sec. 5). In particular, the interpolation is done using an existing interpolation Java API “javax.media.jai api” (JAI).

In this way we achieve the continuous view of field data using incomplete fields as stated in Section 2.

4.2 Multiresolution

Theoretically, we can measure a value of a field at every position inside a geographic space. However, not all resolutions are necessarily relevant. Indeed, according to the type of analysis performed by the user, a more or less detailed resolution can be requested. The multiresolution is an approach that consists in defining resolution levels likely to improve the rendering of the requests made by the user. To model an incomplete field at several resolutions in a multi-dimensional model, we propose two Approaches based on the “Classical Star Schema”: The “field aggregation star-schema” approach and the “field interpolation star schema” approach.

4.2.1 Field Aggregation Star-Schema Approach

Based on the star schema model previously described, we propose a logical schema where the spatial dimension presents different field levels at different resolutions (fig. 5-a). This model extends the spatial dimension of figure 4 with 2 other levels each representing a different level of resolution ([Field].[res200] and [Field].[res400]). Each level of the field dimension is composed of an identifier and a geometry representing a point. The fact table is associated, classically, to the most detailed level of the field dimension. In this way, decision-maker can explore warehoused field data at different resolutions during the same analysis MDX-based session. Only need to change the level of resolution in the query to change the level of details of the result. Using this approach, we use in an MDX query, the appropriate level of resolution of the field dimension as in the following query 1 becomes:

**Query 3:** select average odor for each field member at the 400*400 resolution during 2012

`SELECT [Field].[res400]. Members ON ROWS, {
(time).[2012]} ON COLUMNS
FROM [odorCube]
WHERE [Measures].[value]`

4.2.2 Field Interpolation Star-Schema Approach

As stated in Section 2, in order to provide field data at finer resolutions, spatial interpolation methods can be used. Then, here we propose a variation of the previously proposed schema for handling multiple field resolution levels, by associating the fact table to the field at less detailed resolution as shown on figure 5-b. In our approach moving from fact table values to finer spatial members’ values implies applying spatial interpolation functions. Note that this approach is possible only when dealing with spatial data, because according to the Tobler law geographical position of data can be used for estimating missing values.

Figure 5: (a) Field Aggregation Star Schema (FASS), (b) Field Interpolation Star Schema (FISS)
We have implemented a GeoMDX function in the same way of the function defined in Section 4.1: Numeric-type InterpolateBilinear (Field Member).

However, this function, named “InterpolateBilinear” is prepared to receive as input a field level member instead of geometry and return an interpolated value of this member. We can also see that in this case, the neighbors of each member of a higher resolution than the original one are also stored in the “Field” (Neighbours2, Neighbours3), since members of each resolution are pre-defined in advance, but their values are not since they depend on other dimensions.

Calling this function as follows:

InterpolateBilinear ([Field].res400.CurrentMember)

in the formula of a derived measure, allows to find the values of all the members of the level “res400” (incomplete field at a 400x400 resolution) using their neighbors “Neighbors3”. Thus, the query 3 can be performed as follows:

```
SELECT
  ([Field].res400.Members) ON ROWS,
  ([time].2012) ON COLUMNS
FROM [odorCube]
WHERE [Measures].EstimatedValue
```

While in the multidimensional SOLAP schema, the “InterpolateBilinear” function is called in the “EstimatedValue” calculated measure formula as:

```
formula=“InterpolateBilinear([Field].res400.CurrentMember)“
```

As we can see in the previous query, the call of the calculated measure enables to find the values at a given scale transparently to the decision maker as a classical aggregation (SQL). This approach is motivated by performance issues as described in the next section.

5 Experiments

In this section we detail the performances of the two approaches proposed in Section 4.2 (FASS and FISS) in terms of storage and time computation. The computer used for the following tests has the following configuration: processor Intel® core ™ i3 2,20 GHz, RAM 4 Go, Operating system Windows 7 professional, System OS 64 bits.

In particular, spatial data is stored in PostGIS Spatial DBMS. PostGIS is an open source software that adds support for geographic objects to the PostgreSQL object-relational database. PostGIS follows the Simple Features for SQL specification from the Open Geospatial Consortium (OGC); we use GeoMondrian as a SOLAP server; and JPivot as a client. GeoMondrian is an Open Source Spatial Online Analytical Processing Server.

In order to test our proposal we define different cases where the spatial dimension presents: one field level at the 100*100 resolution; two levels at the resolutions 100*100 and 200*200; and finally three levels at the resolutions 100*100, 200*200 and 400*400. We also vary the size of the temporal dimension in order to understand impact of the spatial and non spatial dimension on performances.

Figure 6-a shows the size of the fact table measured in function of the number of spatial and temporal members (spatial finest resolution / temporal finest granularity) using the two approaches. We can easily see two important differences: i) the field aggregation approach is expensive in terms of storage than the field interpolation one since the latter stores only facts values at a less detailed spatial granularity, ii) in the field interpolation approach the size of the fact table only varies depending on the size of the non spatial dimensions. Thus, even increasing the size of the spatial dimension, the fact table does not change since it contains only measures related to the first level of resolution.

In order to evaluate computation performance we execute the queries previously cited, where we combine roll-up operation on non spatial dimensions, and spatial slice operators over different field resolutions.

Figure 6-b represents the execution time of the query 3, which consists in generating values of the members at different resolutions taking into account different sizes of the time dimension. This figure shows a certain degree of approximation in execution time between the two approaches to a certain level. Beyond this level, we note that the gap widens considerably. Thus, minimizing storage and relations has allowed the field interpolation approach we propose to have better execution time than the field aggregation approach at all resolution levels (100*100, 200*200 and 400*400). Figure 9 shows that the execution time in the “field aggregation approach” increases depending on the number of spatial and temporal members, whereas in the “field interpolation approach”, it increases mainly depending on the number of temporal members. Indeed the size of the spatial dimension does not influence much on performance, since there is no relationship between the fact table and the members who belong to high resolutions.
6 Related work

In order to integrate fields data in a SOLAP model, (Ahmed and Miquel 2005) propose a multidimensional model for handling continuous discrete fields, storing a sample of points as spatial members, to create a discrete cube which is interpolated in the client-side to simulate a continuity. (McHugh 2008) defines new types of dimensions handling fields as a regular grid of squares (raster): “hybrid dimension”, “mixed hybrid dimension”, “mixed matrix dimension” and “geometric matrix dimension”. She also defines the “matrix cube” where facts are cells of the matrix grid. The “field aggregation approach” presented in section 4.2.1 is based on this work. However, the “field interpolation approach” we propose, although it gives the same result, is more efficient in terms of storage and execution time. (Gomez, Gomez et al. 2012) presents a discrete data model for representing continuous fields and an algebra that makes use of OLAP operators (e.g. Dice, Slice, Roll-up, Drill-down ...). However, the discrete model the authors propose does not support the continuous aspect of the field, which consists to retrieve a value for each point with coordinates x and y in the map. In (Gomez, Vaisman et al. 2010), the authors propose a multidimensional model handling fields. They define two types of fields, “field” and “tempfield” (spatial field and temporal field), and semantics for the operators associated to these data types. They include the notion of field dimensions and field measures. They define the “field dimension” as a dimension containing at least one level that is a field (temperature, precipitation…), the “field measure” as a measure represented by a field and the “field hierarchy” as a set of related field levels, which allows a field to be seen at different levels of granularity. They also propose a physical model for data warehouses with continuous fields. However, no implementation has been proposed and the hierarchical relationship between field levels has not been brought to light. (Bimonte and Myoung 2011) provide a multidimensional model that integrates field data independently from their implementation, as measures and dimensions. They also present a formal representation of the spatio-multidimensional model schema where they define the concepts of field dimensions, field measures, and field views. To our knowledge, no implementation including the continuous appearance of incomplete field or the multiresolution over incomplete fields has been proposed.

Representation of multidimensional data under different resolution levels or scales may be considered as multirepresentation. (Bernier, Bédard et al. 2005) proposes an approach to provide on-Demand multi-scale maps. Although this approach models maps features at different scales by using spatial hierarchies, but it does not contain measures. (Yvan, Proulx et al. 2002) defines a UML-based conceptual model that integrates multiple geometric and semantic representations properties of spatial levels. However, this work does not present a complete multidimensional model with facts and hierarchies. Moreover, (Bédard et al., 2002) suggests (without providing details) using a different spatial data warehouse for each representation. Therefore, changing the representation corresponds to move to another spatial data warehouse. (Gascueña and Guadalupe 2009) propose a conceptual model with a multi-representation of spatial members. They also
propose a physical schema, but any implementation into a classical ROLAP architecture is presented. Finally, (McGuire, Gangopadhyay et al. 2008) define a snowflake schema for an environmental application where three dimensions represent the same spatial members at different resolutions.

7 Conclusion and future work

In this paper we present a multidimensional model for incomplete fields at several resolutions and its implementation in a SOLAP architecture based on standards (e.g. SQL and MDX). We are working on using spatial data mining to speed-up map algebra operations and implement a SOLAP visualization client. We also work in integrating other interpolation functions to generalize the proposed approach.
