HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
USING ACCELERATION SENSORS TO IDENTIFY RIGIDITY RELEASE THRESHOLD DURING DEEP BRAIN STIMULATION SURGERY

Background
Deep brain stimulation (DBS) is now a widely accepted surgical treatment for Parkinson’s disease (PD). Electrodes are implanted in the patient’s brain after intraoperative test stimulation. Changes in parkinsonian rigidity during test stimulation are detected by an evaluator, usually a neurologist, by identifying changes in the resistance of the patient’s arm to a passive movement. When a stimulation-induced reduction in rigidity is observed, the stimulation amplitude is noted; this is the clinical rigidity release threshold. The aim of the present study was to test the hypothesis that, at the moment of reduction in rigidity, the speed with which the evaluator moves the patient’s arms increases, and that this change and its amplitude can be detected with an acceleration sensor.

Methods
Step 1: Data recording setup. A 3-axis accelerometer evaluation board (STEVAlMK022V1, ST) housed in a non-conductive printed plastic case (FullCure 830 Vero White, Objet Geometries Ltd) is mounted on the patient’s wrists using a Velcro strap. The sensor is connected to a laptop with in-house developed recording software. This software is also connected to the deep brain stimulation system which provides current during the test stimulations.

Step 2: Synchronization of two data sets. Accelerometer data is recorded during all test stimulations in synchronization with the electrophysiology system.

Results
• Three statistical features were identified to well describe rigidity release (Standard Deviation, Signal Energy and Spectral Amplitude of the Peak Frequency)
• Out of the 190 test stimulations, rigidity release thresholds were found using the clinical method for 144 evaluations, while using quantitative method, 160 thresholds were found. For 138 test stimulations, thresholds were found using both the methods.
• The rigidity release thresholds found using accelerometer evaluation are significantly lower than those found clinically (Fig 5).

Discussion
• The additional acceleration measurements during the surgery did not increase operation time or the patient’s discomfort.
• Sufficient baseline data is necessary for proper identification of acceleration thresholds.
• There is an inherent subjective component in the acceleration analysis because the evaluation is done by the neurologist.
• Further analysis in relation to anatomy could result in better target structures and could raise additional knowledge of the mechanisms of action of DBS.

Conclusion
• The acceleration of the neurologist’s movement is inversely proportional to change in patient’s rigidity.
• Acceleration measurements confirm the subjective evaluation, but they seem to be more sensitive (Fig 5).
• Quantitative rigidity evaluation is feasible during DBS surgery.
