Abstract

We analyse the influence of the recent wave of migration on the incidence of poverty among stayers in Ecuador. We draw our data from a survey that provides detailed information on migrants. The analysis reveals a significant negative effect of migration on poverty among migrant households. This effect is substantially smaller than the one that we find focusing on recipient households. We explore the factors that account for this divergence. Our analysis entails that the existing empirical evidence on the relationship between remittances and poverty needs not to be informative about the size of the direct poverty-reduction potential of migration.

Keywords: remittances; household-level data; poverty; propensity score matching.

JEL codes: F22; O15; I32.

1 Introduction

What is the influence exerted by international migration on the poverty status of the household members left behind? Providing an answer to this question requires comparing the observed incidence of poverty for migrant households¹ with the one prevailing in a counterfactual scenario where all household members stay at home. The economic literature has been mostly focusing on a related but distinct research question, namely the analysis of the relationship between the receipt of migrants' remittances and the incidence of poverty among stayers (Gustafsson and Makonnen, 1993; Leliveld, 1997; Acosta *et al.*, 2006, 2008; Yang and Martinez, 2007; Lokshin *et al.*, 2010; Adams and Cuecuecha, 2013).² Still, the “growing view in the literature that remittances can have a positive impact on economic development by reducing poverty” (Adams and Cuecuecha, 2013, p. 38) needs *not* to be informative about the size of the direct poverty-reduction potential of international migration. This is due to the analytical choice of some of the papers in the literature to analyse the effects of remittances while taking migration decisions as given, and to the non coincidence of the group of migrant and of recipient households.

Specifically, Gustafsson and Makonnen (1993), Leliveld (1997) and Adams and Cuecuecha (2013) compare the observed incidence of poverty among recipient households with the incidence that would have prevailed in a hypothetical scenario with no remittances but with an unchanged household composition. Other papers analyse a no remittances *and* no migration counterfactual, and the choice to focus on the relationship between the receipt of remittances and the incidence of poverty among stayers appears to be data-driven as the data either do not allow to identify migrant households (Acosta *et al.*, 2006, 2008) or they just provide information on the migrants that send remittances (Lokshin *et al.*, 2010). The econometric evidence provided by these papers is informative about the poverty-reduction potential of international migration only if the receipt of remittances represents a good *proxy* for the unknown migration status of the household, but there are theoretical and empirical reasons why this is unlikely to be the case.

From a theoretical perspective, the so-called new economics of labor migration portrays migration as a joint decision of the migrant and of some group of stayers, where remittances ensure that the monetary returns from migration are shared with the non-migrants that contributed to finance the cost of the move. This group can extend beyond the household of origin of the migrant, so that some recipient households are *not* migrant households.

Similarly, not all migrant households are also recipient households,³ as the migrant might be unable or unwilling to abide to the “implicit contractual arrangement” she had agreed upon with the stayers (Stark and Bloom, 1985). For instance, migrants could experience spells of unemployment that prevent them from sending remittances, or they might deliberately decide not to transfer any money back home. The partial, and possibly limited, overlap between the groups of recipient and migrant households suggests to be wary of interpreting the available empirical evidence in the literature as being informative about the direct effect of international migration on poverty at origin. This effect depends on (i) the change in total household income from domestic sources due to migration, (ii) the variation in the number of household members residing at origin due to migration, and (iii) the remittances sent back by the migrants.

Our paper analyses the effect of migration upon the incidence of income poverty among stayers in Ecuador, a country that experienced an unprecedented wave of international migration induced by a severe economic crisis at the end of the 1990s. The poverty headcount rose by an estimated 2 million people between the mid- and the late-1990s (Parandekar *et al.*, 2002) in a country with a population of 12.7 million. More than half a million Ecuadorians left the country within a few years’ time, mostly heading toward Spain and the US. The sorting of Ecuadorian migrants across destination and their pattern of selection on education were shaped by the combined effect of the crisis-induced liquidity constraints and of the high migration costs that Ecuadorian would-be migrants faced, which were partly policy-induced (Bertoli *et al.*, 2011). Specifically, most of the recent migrants opted for Spain, where they enjoyed substantially lower income gains than in the US but where a bilateral visa waiver that had been granted since 1963 reduced the monetary costs of migration (Bertoli *et al.*, 2013). Survey data collected in Spain reveal that the cost of migrating from Ecuador amounted on average to \$1,800 (Bertoli *et al.*, 2011); although this figure stands substantially below the estimated \$7,000-\$9,000 of attempting to migrate illegally to the US (Jokisch and Pribilsky, 2002), it still hindered both the participation of poor households to this migration wave and its ensuing influence on poverty at origin.

We draw the data for our analysis from the the *Encuesta Nacional de Empleo, Desempleo y Subempleo*, ENEMDU, conducted by the INEC in December 2005. This labor market survey allows us to derive income-based definitions of poverty and it provides detailed information on migrant members, including the year of migration, age, gender, education and

the amount of remittances sent over the previous 12 months. The availability of rich data on migrants represents a key value added of this survey, as our analysis exploits the information on the timing of the various migration episodes and the information on the individual characteristics of the migrants.

Specifically, the ability to identify migrant and not just recipient households allows us to directly analyse the relationship between international migration and poverty, and to compare our results with the ones that we obtain when we follow the more standard approach in the literature, which relies on the receipt of remittances as a *proxy* for the unobserved migration status of the household.⁴ Furthermore, the information on the timing of the migration episodes allows us to define the treatment of interest as having sent at least one member abroad after 1998, the year that marks the start of the Ecuadorian crisis (Beckerman and Cortés-Douglas, 2002; Jácome, 2004). This allows us to greatly reduce the heterogeneity of the influence on poverty that would arise if the group of treated households was based on migration episodes that are more distant in time, and it also reduces the strength of the effects of migration on the supply (Mishra, 2007) or on the demand side (Woodruff and Zenteno, 2007; Wahba and Zenou, 2012; Marchetta, 2012) of the labor market at origin that can indirectly influence non-migrants.

We resort to propensity score matching, PSM, to identify the effect of migration on poverty, as we lack a credible instrument for migration, and as this estimation technique does not require to introduce assumptions on the functional form of the relationship between household characteristics, migration and poverty. This estimation approach has been recently applied to the analysis of the effects of migration and remittances by, *inter alia*, Cox-Edwards and Rodríguez-Oreggia (2009), Acosta (2011) and Jimenez-Soto and Brown (2012), although we acknowledge that the debate around its ability to produce unbiased estimates is still open (Dehejia, 2005; Smith and Todd, 2005a,b; Peikes *et al.*, 2008). This is why we test the sensitivity of our estimates to possible departures from the identifying assumption following Rosenbaum (2002) and Becker and Caliendo (2007).

Our empirical analysis reveals that the recent Ecuadorian migration reduced the incidence of poverty among migrant households by an estimated 17.4-20.8 percent. This effect is statistically significant, although sensitive to possible violations of the identifying assumption of selection on observables.

The ENEMDU 2005 survey also allows us to identify recipient households independently

from the questions related to migrants, as the income section of the questionnaire provides information related to the receipt of remittances from abroad over the month before the survey. When, as the literature does, we focus on recipient households, we find sharply different results, as the treatment is estimated to induce a decline in poverty by 57.2-59.2 percent. These estimates, which are in line with those obtained by Acosta *et al.* (2008) with data drawn from the 2004 round of the ENEMDU, entail that the poverty-reduction potential of international migration cannot, in the case of Ecuador, be inferred from the existing econometric evidence on the relationship between the receipt of remittances and poverty, and our paper explores the factors that can account for such a divergence in the results.

This paper is closely related to four different strands of literature. First, it draws on the papers that analyse the impact of migration and remittances on poverty at origin with household-level data (Yang and Martinez, 2007; Acosta *et al.*, 2006, 2008; Lokshin *et al.*, 2010; de la Fuente, 2010; Jimenez-Soto and Brown, 2012; Adams and Cuecuecha, 2013) and that estimate counterfactual domestic earnings for the migrants (Adams, 1989; Barham and Boucher, 1998). Second, it is related to the papers that analyse the determinants of migrants' selection (Chiquiar and Hanson, 2005; McKenzie and Rapoport, 2010; Fernández-Huertas Moraga, 2011, 2013). Third, it is connected to the vast literature on PSM originating from the seminal contribution by Rosenbaum and Rubin (1983), and in particular to the papers that deal with the use of sampling weights (Frölich, 2007; Zanutto, 2006) and with departures from the identifying assumptions (Becker and Caliendo, 2007; Ichino *et al.*, 2008; Nannicini, 2007). Fourth, this paper contributes to the strand of literature analyzing the determinants and the effects of the recent wave of Ecuadorian migration (Beckerman and Cortés-Douglas, 2002; Jokisch and Pribilsky, 2002; Jácome, 2004; Gray, 2009; Calero *et al.*, 2009; Bertoli, 2010; Bertoli *et al.*, 2011, 2013).

The rest of the paper is structured as follows: Section 2 briefly describes the PSM technique, and Section 3 discusses its implementation to the analysis of the effect of migration on poverty. The data source and the descriptive statistics are presented in Section 4. Section 5 presents the estimates and it explores the difference between the results obtained when focusing on migrant or on recipient households, and Section 6 concludes.

2 Propensity score matching

Households can be either subject to a treatment, $z_i = 1$, or not, $z_i = 0$, with T (U) denoting the subsample of treated (untreated) units. Let y_{i1} be the value of the outcome variable when $z_i = 1$, and let y_{i0} represent its value when $z_i = 0$. The observed value of the outcome variable y_i is related to its potential outcomes by the observation rule:

$$y_i = z_i y_{i1} + (1 - z_i) y_{i0}$$

The treatment effect on the unit i is defined as $\tau_i = y_{i1} - y_{i0}$. The average treatment effect on the treated, ATET, is defined as:

$$E_T(\tau_i | z_i = 1) = E_T(y_{i1} | z_i = 1) - E_T(y_{i0} | z_i = 1) \quad (1)$$

where E_T denotes the average on treated units only. The observational rule for y_i precludes the estimation of the ATET, as y_{i0} is not observed when $z_i = 1$. In an experimental setting, we have that $E_U(y_{i0} | z_i = 0) = E_T(y_{i0} | z_i = 1)$, so that observed outcomes for the untreated units can substitute for the unobserved outcomes y_0 for treated units. With non-experimental data, this does not hold true because the assignment to the treatment can be influenced by a vector \mathbf{x} of covariates that also exert an influence on y .

Assume that the vector \mathbf{x} includes all covariates that have a simultaneous influence on the treatment and on the outcome, so that the potential outcome y_0 is independent from z conditional upon \mathbf{x} . Formally:

$$y_0 \perp\!\!\!\perp z | \mathbf{x} \quad (2)$$

where the symbol $\perp\!\!\!\perp$ denotes statistical independence. Let $f(\mathbf{x})$ represent the probability of assignment to treatment, which is also called the *propensity score*. The seminal contribution by Rosenbaum and Rubin (1983) demonstrates that if $f(\mathbf{x}) \in (0, 1]$ and (2) holds, then we also have that:

$$y_0 \perp\!\!\!\perp z | f(\mathbf{x}) \quad (3)$$

The outcome y_0 is independent from the assignment to treatment z conditional upon $f(\mathbf{x})$, as $f(\mathbf{x})$ represents a balancing score that ensures that $\mathbf{x} \perp\!\!\!\perp z | f(\mathbf{x})$ (Rosenbaum and Rubin, 1983). This, in turn, implies that the expected value of the unobserved outcome y_0 for treated units conditional upon $f(\mathbf{x})$ coincides with the expected value of the observed outcome y_0 for untreated units:

$$E_T[y_{i0} | z_i = 1, f(\mathbf{x}) = p] = E_U[y_{i0} | z_i = 0, f(\mathbf{x}) = p]$$

Hence, the ATET can be estimated through an iterative averaging procedure:

$$\widehat{E}_T(\tau_i|z_i = 1) = \int_0^1 \left[E_T(y_{i1}|z_i = 1, f(\mathbf{x}) = p) - E_U(y_{i0}|z_i = 0, f(\mathbf{x}) = p) \right] g(p) dp \quad (4)$$

where $g(p)$ denotes the distribution of the propensity score over the subsample T .

3 Implementation

We discuss here the key steps of the implementation of PSM to the analysis of the effect of migration on poverty for Ecuadorian households.⁵ The treatment z_i is represented by having a household member who migrated, while the outcome y_i is given by the income poverty status.

3.1 Selection of the covariates

The first step is related to the identification of the variables that belong to \mathbf{x} , as this vector has to include only variables that have a simultaneous influence on the probability to have a migrant member and upon the poverty status of the household. Variables that only have an impact on the probability to migrate should not be included, as the objective of the estimation of the propensity score is not to maximize the fit of the model (Caliendo and Kopeinig, 2008). The inclusion in \mathbf{x} of variables that influence exclusively the treatment would actually reduce the ability of the estimated propensity score to serve as a balancing score.

The effect of migration on poverty is identified under the assumption that, conditional upon \mathbf{x} , the decision to migrate is not systematically related to the poverty status of Ecuadorian households. As this is a strong identifying assumption, we discuss in Section 3.6 how to assess the sensitivity of our estimates to violations from the assumption of selection on observables.

3.1.1 Post-treatment measurement of the covariates

Rosenbaum and Rubin (1983) write that the analysis should be based only on variables that are measured before the treatment so to avoid any endogeneity with respect to the exposure to the treatment itself, but Lechner (2008) demonstrates that this requirement can actually

be relaxed, specifying the conditions under which the reliance on post-treatment covariates does not bias the estimate of the ATET. Specifically, the influence of the treatment on the covariates should be non-systematic, so that observing them after the treatment only induces a measurement error in \mathbf{x} . If the distribution of the elements of \mathbf{x} depends on the exposure to the treatment, then the estimate of the ATET will be biased.

This is why the availability of data on *all* household members, irrespective of whether they migrated or not, is crucial for the analysis: if migrants are *not* randomly selected within the household with respect to their gender, age and education, then any measure of the demographic structure or of the average level of education of the household would be endogenous to migration,⁶ precluding its inclusion in the analysis.⁷ Any demographic event other than migration, could also drive a wedge between the household characteristics measured before or after our reference period. A sensitivity of parental decisions on fertility and education with respect to the prospect to migrate (Mountford and Rapoport, 2011; Docquier and Rapoport, 2012), to actual migration (Yang, 2008) or to the transfer of norms between countries (Beine *et al.*, 2013; Bertoli and Marchetta, 2013) could introduce a systematic correlation between the treatment and post-treatment measures of the demographic structure of the household and of the average level of education of its members.

The empirical relevance of these concerns can be mitigated by focusing on a *recent*, and mostly unanticipated, treatment and by measuring household education only on adult members, whose education decisions should have not been affected by the receipt of remittances. No Ecuadorian province with the exception of Azuay and Cañar,⁸ representing just 6 percent of the Ecuadorian population, had a long-standing tradition of migration, which would greatly magnify the relevance of the concerns about the systematic influence of the treatment on education and demographic variables.⁹ This is why we are confident that we can safely draw on Lechner (2008) to justify the inclusion of some post-treatment measures in the analysis.

While the literature often includes variables that relate to the household head,¹⁰ we chose not to do so as household headship can be endogenous to migration, as observed by Cox-Edwards and Rodríguez-Oreggia (2009), and the ENEMDU 2005 does not provide information that could be used to identify the household head in the counterfactual no migration scenario. The *Encuesta de Condiciones de Vida* conducted by the INEC in 2006 reveals that 20.8 percent of the migrants were household heads. For similar reasons, we also

opted for omitting measures of asset holdings from \mathbf{x} , as Bertoli (2010) provides evidence of their endogeneity with respect to the time elapsed since migration.¹¹

3.2 Estimation of the propensity score

The propensity score $f(\mathbf{x})$ is not known, and it is estimated through a logit model, so that the probability of assignment to the treatment is estimated as:

$$f(\mathbf{x}) = \frac{e^{\mathbf{x}'\beta}}{1 + e^{\mathbf{x}'\beta}}$$

The coefficients of the estimated propensity score do not have a behavioral interpretation (Dehejia and Wahba, 2002), so that they should not be regarded as reflecting the effect of the elements of \mathbf{x} upon the probability to have a migrant member. The functional specification of the estimated propensity score $\hat{f}(\mathbf{x})$ is only meant to ensure that $\hat{f}(\mathbf{x})$ acts as a balancing score of the covariates, and this can call for the inclusion of higher-order and interaction terms between the elements of \mathbf{x} (Caliendo and Kopeinig, 2008). For the same reason, sampling weights are not used in the estimation of $\hat{f}(\mathbf{x})$, as this is not meant to support inferences about the underlying population (Zanutto, 2006; Frölich, 2007).

3.3 Check of the balancing property

The literature offers different approaches to the necessary evaluation of the ability of $\hat{f}(\mathbf{x})$ to serve as a balancing score. One can perform a t -test on the null hypothesis of the equality of the mean, conditional on the value of $\hat{f}(\mathbf{x})$, of each of the elements in \mathbf{x} in the groups of treated and untreated units. This approach is exposed to two critiques. First, the balancing property should be verified not on the whole sample of observations, but on the subsample that is used to estimate the ATET, so that the ability of $\hat{f}(\mathbf{x})$ to serve as a balancing score is closely intertwined with the choice of the matching method (Lee, 2013). Second, Imai *et al.* (2008) regard the reliance on hypothesis testing as a “balance test fallacy”, as “balance is a characteristic of the sample, not some hypothetical population, and so, strictly speaking, hypothesis tests are irrelevant in this context” (Imai *et al.*, 2008, p. 497). The logic that underlies hypothesis testing is that there is threshold level below which the imbalance of the covariates can be accepted, while “imbalance with respect to observed pre-treatment covariates [...] should be minimized without limit where possible” (Imai *et al.*, 2008, p. 497), and parametric methods could be used to adjust for any residual imbalance (Ho *et al.*, 2007).

Hence, we follow Sianesi (2004) and re-estimate the propensity score on the matched sample alone: the difference between the pseudo- R^2 on the unmatched and matched sample gives us a measure of the extent to which the estimated propensity score $\hat{f}(\mathbf{x})$ effectively balances the covariates. If $\hat{f}(\mathbf{x})$ balances the covariates in the subsample of treated and control observations, then the logit model should be poorly able to predict assignment to the treatment when estimated on matched observations only.

Following the arguments by Imai *et al.* (2008), we also compute the ATET with the adjustment for the residual imbalance of the covariates \mathbf{x} proposed by Abadie *et al.* (2004) as discussed in Section 3.5 below.

3.4 Matching methods

The propensity score greatly reduces the “curse of dimensionality” that characterizes matching methods (Caliendo and Kopeinig, 2008), but the exact matching on $\hat{f}(\mathbf{x})$ that would be required by the estimation of the ATET according to (4) is nevertheless unfeasible, and we need to resort to approximate matching techniques. Specifically, we rely on n -nearest neighbor matching, adjusting the matching technique to account for the sampling weights w_i associated to each household in the ENEMDU 2005 following Abadie *et al.* (2004).

Specifically, let w_T represent the average sampling weight of migrant households in the sample. With n -nearest neighbor matching, with $n \geq 1$, each migrant household i is matched with a set $C_n(i)$ non-migrant households whose estimated propensity score is nearest to $\hat{f}(\mathbf{x}_i)$, and whose sum of sampling weights is equal to nw_T . Matching is performed only on the subsample of treated and untreated units that belong to the common support, defined as the closed subset of the interval $[0, 1]$ where the density of the estimated propensity score $\hat{f}(\mathbf{x})$ is positive both for migrant and non-migrant households.

3.5 Estimation of the ATET

Sampling weights are not used in the estimation of $f(\mathbf{x})$, as discussed in Section 3.2 above, while they are used in the estimation of the ATET. This, as described in (4), is the result of an iterative averaging procedure: following Zanutto (2006) and Frölich (2007), sampling weights w are used when we compute the counterfactual poverty status y_0 for each migrant

household. Specifically, we compute it as:

$$\widehat{y}_{i0} = \frac{\sum_{j \in C_n(i)} w_j y_{j0}}{\sum_{j \in C_n(i)} w_j}$$

Letting T' represent the subset of migrant household for which the set of matched control units is non-empty, the ATET is computed as:

$$\widehat{E}_T(\tau_i | z_i = 1) = \frac{\sum_{i \in T'} w_i (y_{i1} - \widehat{y}_{i0})}{\sum_{i \in T'} w_i} \quad (5)$$

The estimation of the effect of migration on poverty following (5) is the outcome of a two-step procedure, and the estimation of the standard error of $\widehat{E}_T(\tau_i | z_i = 1)$ should also reflect the uncertainty that is due to the estimation of the propensity score $\widehat{f}(\mathbf{x})$. Abadie and Imbens (2008) argue that the reliance on bootstrapping to derive the standard error associated to (5) lacks theoretical justifications, and it can fail to produce an unbiased estimate of the true standard error. Hence, following their suggestion, we rely on the analytical standard errors proposed by Abadie and Imbens (2008) and implemented in Stata by Abadie *et al.* (2004) to derive correct confidence intervals around our point estimates.

We follow Abadie *et al.* (2004) also with respect to the estimation of the ATET through an OLS regression of the observed outcome variable y_i on the treatment z_i and on the vector \mathbf{x}_i on the subsample of matched households in order to correct for the residual imbalance in the covariates.¹²

3.6 Sensitivity to departures from selection on observables

The identification of the effect of the treatment z through PSM is based on the assumption of *selection on observables*, reflected in (3). The plausibility of this assumption can be defended on the basis of the relevant theoretical and empirical literature, but it cannot be tested, as observed data are uninformative about the relationship between the treatment z and the potential outcome y_0 . Nevertheless, it is possible to assess the robustness of the estimated ATET with respect to *possible* violations of (3), following the approach proposed by Becker and Caliendo (2007).¹³

Specifically, Becker and Caliendo (2007) assume that the distribution of a binary outcome y_0 conditional on the propensity score $f(\mathbf{x})$ is *not* independent from the assignment to treatment z , while independence would hold conditional on the propensity score estimated

on \mathbf{x} plus an unobserved dichotomous variable u :

$$y_0 \perp\!\!\!\perp z | f(\mathbf{x}, u) \quad (6)$$

This implies that the ATET estimated on the basis of matching on $\widehat{f}(\mathbf{x})$ does not represent the true causal effect of the treatment z upon the outcome y for the treated units, as it is confounded by the non-random selection on the unobservable u of the treated households. If:

$$f(\mathbf{x}, u) = \frac{e^{\mathbf{x}'\beta + \gamma u}}{1 + e^{\mathbf{x}'\beta + \gamma u}}$$

then, for two households with identical values of the covariates \mathbf{x} , we have that the ratio of their actual odds of exposure to the treatment z belongs to the interval $[e^{-\gamma}, e^{\gamma}]$: only if u has no impact on $f(\mathbf{x}, u)$, i.e., $\gamma = 0$, then the two observationally identical households have the same probability of exposure to z . Becker and Caliendo (2007) rely on the test statistic proposed by Mantel and Haenszel (1959) to evaluate the effect of u on the significance of the estimated ATET for different values of e^{γ} , which reflect different assumptions about the *possible* impact of u upon the probability of exposure to the treatment.

For instance, if we estimate a negative impact of international migration upon the incidence of poverty, it is interesting to test whether this result might reflect a positive selection of migrant households on an unobservable characteristic that is positively correlated with their income generating capacity. The Mantel and Haenszel (1959) test statistic tells us how strong can be the influence of this unobservable u before we are induced not to reject the null hypothesis that the effect of international migration upon poverty is actually zero. This test does *not* tell us whether such a bias due to an unobservable factor does exist (Becker and Caliendo, 2007), but only how strong such a *possible* bias would need to be in order to make the estimated results sensitive to a departure from the underlying identifying assumption.

4 Data and descriptive statistics

This ENEMDU 2005 survey, which was conducted on a sample of 18,357 households, contains a module providing information on the household members who had moved abroad and were absent at the time of the survey. The data on migrants include age, gender, level of education, year of migration and country of destination; this allows us to identify all Ecuadorians who left after the late 1990s economic crisis, provided that at least one household member was still in Ecuador at the time of the survey.

Whole household migration leads to an undercount of recent Ecuadorian migrants, which does not represent a reason for concern given that, as the literature does, we are interested in identifying the effects of migration on the incidence of poverty among stayers. Furthermore, interviewees might have been reluctant to disclose information on migrant members; reassuringly, Bertoli (2010) demonstrates that the observable characteristics of the Ecuadorian migrants obtained from the ENEMDU 2005 do not differ from those that can be obtained from US or Spanish sources, so that the undercount of the migrants does not pose a threat to identification.

We restrict the sample to households that *(i)* do not have any returnee or foreign-born among their members, and that *(ii)* do not have a migrant who left before our period of analysis (1998-2005). This ensures that our sample includes only households with no migration experience before the late 1990s economic crisis. We further restrict the sample to *(iii)* non migrant households who report not to have received remittances in the month before the survey,¹⁴ and we exclude from the sample households with missing or outlying data on income.

The ENEMDU 2005 provides information on labor and non-labor earnings, including public and private transfers. The questionnaire contains two distinct questions with respect to remittances: first, all households are asked whether they received remittances from abroad, and the reported amount refers to the same recall period as for all other income sources, namely the month before the survey. Second, the households that report having at least one migrant member are asked about the amount of remittances received from each migrant over the previous 12 months, and about the number of transfers over which this amount was distributed.

Total income for migrant households is defined as the sum of all incomes from domestic sources reported for November 2005 *plus* the average monthly amount of remittances received over the year before the survey from the migrants. The survey reveals that the migrants who send remittances to their households in Ecuador realize, on average, seven transfers per year, and this implies that the remittances received in the month before the survey overstate what households receive on average, as the high and regressive transfer costs induce migrants to concentrate their remittances in a limited number of transfers.

Our final sample includes 16,089 households, with 832 households with at least one migration episode between 1998 and 2005. Table 1 presents the relevant descriptive statistics.

Migrant households have on average 1.35 migrants abroad, with 63.4 and 23.1 percent of them having a migrant in Spain and in the US respectively.

The data reveal that 29.2 percent of the migrant households did *not* receive remittances in the 12 months before the survey. We defined the subsample of migrant households as including all households that sent at least one migrant abroad between 1998 and 2005, and this implies that some migration episodes actually occurred close to the time of the survey. If we exclude the households who sent their first member abroad in the two years before the survey, the share of non recipient still stands at 26.0 percent.

The incidence of income poverty, defined on the basis of the poverty line set by the INEC,¹⁵ stands at 20.9 percent for migrant households; this figure is substantially below the 36.1 percent that we obtain when defining poverty on the basis of non-remittance income only.¹⁶ Still, remittances do not represent a revenue that adds up to other exogenous income sources, and they at least partly compensate for the foregone domestic earnings of the migrants,¹⁷ and the labor supply decisions of stayers can be endogenous with respect to migration (Chami *et al.*, 2005; Amuedo-Dorantes and Pozo, 2006; Cox-Edwards and Rodríguez-Oreggia, 2009; Binzel and Assaad, 2011). This suggests regarding the incidence of poverty among non migrant households to get a first sense of the impact of migration on poverty. This, as reported in Table 1, stands at 32.2 percent; this implies that the share of poor households is 35.1 percent lower among migrant than among non migrant households. The descriptive statistics reveal that the two groups of households differ with respect to relevant observable characteristics that are likely to be associated both on their poverty status and on the probability to have a migrant. Specifically, a smaller share of the households with at least one member who migrated between 1998 and 2005 reside in rural areas, they have a larger household size and a smaller dependency ratio, and their members are better educated. Migrant households have working age members with 9.6 years of schooling, while the corresponding figure for non migrant households stands at 8.4 years, in line with the econometric evidence on the determinants of individual self-selection into migration provided by Bertoli (2010) and Bertoli *et al.* (2011, 2013). Unsurprisingly, the households who recently sent one of their members out of Ecuador have also a better connection with migration networks, proxied by the share of households in each county with a migrant to the US before 1998.

The variables related to the demographic and schooling characteristics for migrant house-

holds can be defined either on the basis of all household members, as we did in Table 1, or on the basis of resident members alone. Table 2 reveals that the exclusion of the data on migrant members blurs most of the differences in observables between the two groups of households; beyond the mechanical impact on household size and on the number of working age members, Table 2 shows that migrants are positively selected on education *within* the household, as the average number of years of schooling falls from 9.6 to 8.7 when we exclude migrant members, and the share of households with at least one college graduate falls from 25.02 to 12.95 percent, with the latter figure coinciding with the one for non-migrant households reported in Table 1. This reinforces the empirical relevance of the need to have information on the individual characteristics of migrants, and it gives us a picture of Ecuadorian migrants that differs from the one assumed by Acosta *et al.* (2008). This, in turn, has relevant implications for the econometric analysis, as the number and level of education of the migrants clearly exerts an influence upon the poverty status of migrant households in the counterfactual scenario with no migration.

5 Estimates

5.1 Migration and poverty

The treatment z is represented by having at least one household member who left Ecuador between 1998 and 2005, and the outcome y is represented by the poverty status of the household, defined on the basis of the national poverty line.¹⁸ We retain the following household characteristics in the vector \mathbf{x} of covariates that is used to estimate the propensity score $f(\mathbf{x})$: the number of working age members, the dependency ratio, the share of female working age members, the average years of schooling, a dummy indicating if a household member completed tertiary education, a dummy signaling indigenous self-identification, the county-level size of migration networks,¹⁹ a dummy for residence in rural areas.²⁰

The choice of the elements of \mathbf{x} , which is constrained by the reasons exposed in Section 3.1.1, is driven by the evidence that emerges from the economic literature. Specifically, the inclusion of variables related to the level of education of the household is motivated by the evidence of large returns to schooling on the Ecuadorian labor market (Bertoli *et al.*, 2011) and of the positive selection on education of recent migrants (Bertoli, 2010). The number and the gender composition of working age members can influence both the probability to send

one its members abroad (Acosta *et al.*, 2007), and it can also be directly related to household income per capita, as the labor productivity in family-run activities is not constant—and labor supply decisions of the household members are mutually interdependent, and Ecuador is characterized by a large gender gap in wages (see, for instance, Bertoli *et al.*, 2013). Geographical factors can shape both the opportunity to migrate and the local incidence of poverty, which is highest in rural areas (Hentschel *et al.*, 2000). Similarly, indigenous households could be, for linguistic and cultural reasons, less likely to migrate, and are also exposed to a higher incidence of poverty (Parandekar *et al.*, 2002).²¹

The overall goodness of fit, measured by the pseudo- R^2 , of the logit model stands at 0.124, and specification (1) in Table 3 reports the coefficients that are used to generate the propensity score.²² The estimated propensity score $\hat{f}(\mathbf{x})$ is then used to define the subsample of non-migrant households that form the control group, and to estimate the ATET. Table 4 reports the results obtained with nearest neighbor matching, with a number of matches $n = 1, \dots, 10$. The estimation of $\hat{f}(\mathbf{x})$ on the subsample of matched households only is characterized by a pseudo- R^2 that is 89.8 to 98.3 percent lower than on the whole sample. The reduction in the pseudo- R^2 is increasing in the number of matches n , and it already stands at 96.3 percent when $n = 3$, and this is reassuring with respect to the ability of $\hat{f}(\mathbf{x})$ to act as a balancing score.

Table 4 reports the estimated ATET: for $n \geq 3$, migration induces a decline in the incidence of income poverty between 2.8 and 3.7 percentage points, a figure that stands substantially below the 11.1 percentage points difference reported in Table 1. This suggests that differences in observables, which are controlled for through the matching procedure, account for a large part of the lower incidence of poverty among the households who sent at least one of their member abroad after 1998. Furthermore, the null hypothesis that the ATET is equal to zero can be marginally rejected only for $n \geq 6$.

The estimated ATET increases by 1.3-1.6 percentage points for $n \geq 3$ when we adopt the regression-based approach proposed by Abadie *et al.* (2004): the estimates for the bias-adjusted ATET range between -4.4 and -5.5 percentage points, and the null hypothesis that the true effect is zero can always be rejected at least at the 5 percent confidence level. The upper bound of this range implies that migration induced a reduction in the incidence of poverty by 20.8 percent among migrant households. These estimates suggest that differences in observable characteristics can explain no less than half of the observed difference in the

incidence of poverty between migrant and non-migrant households.²³

What about possible differences in unobservable characteristics? Table 4 reports the results from the Mantel and Haenszel (1959) test statistic; specifically, it reports the highest values of e^γ that still allow to reject at the 5 or 10 percent confidence level the null hypothesis that the effect of the treatment is zero, with the estimated effect on poverty actually reflecting only a positive selection on unobservables. For $n \geq 3$, the estimated ATET is still negative and significant at the 5 percent confidence level for values of e^γ ranging between 1.15 and 1.25. This, in turn, implies that an unobserved variable that drives a wedge of 30 percent in the probability to select into migration for otherwise observationally identical households would suffice to fully account for the estimated effect of migration on poverty.

While the test proposed by Becker and Caliendo (2007) is silent about the existence of such a variable, as the conditional independence assumption in (3) is untestable, it suggests that the estimated effect of migration on poverty in Ecuador might reflect even a moderate extent of positive selection on unobservables. The exclusion from the vector \mathbf{x} of covariates of any measure of household assets, which is due to the endogeneity of the asset holdings observed at the time of the survey (Bertoli, 2010) and to the absence of retrospective information, implies that concerns about a possible non-random selection on unobservables cannot be readily dismissed. This, in turn, suggests that the ability of the recent wave of migration to reduce the incidence of income poverty in Ecuador might have been limited.

5.2 Remittances and poverty

The survey also allows us to define the treatment as the receipt of remittances. As discussed in Section 4, all households in the sample are asked whether they received remittances from abroad in the month before the survey, as in Acosta *et al.* (2006, 2008), irrespective of whether they report to have a migrant member.²⁴ We can then define the income of recipient households as the sum of incomes from all sources, including remittances, reported for November 2005.

No information is provided on the characteristics of the sender of remittances; we introduce the same hypotheses as Rodriguez (1998) and Acosta *et al.* (2008), namely that remittances are sent by one male adult, with the same level of education as non-migrant adults. The incidence of poverty among recipient households stands at 12.8 percent, significantly below the 20.9 percent that characterizes migrant households and 19.2 percentage

points below the corresponding figure for non recipient households.

Specification (2) in Table 3 reports the estimated propensity score $\hat{f}(\mathbf{x})$, and Table 5 reports the estimated ATET. With respect to $\hat{f}(\mathbf{x})$, we can observe the change in the estimated coefficients for the two variables that describe the level of education of the households: the dummy for college education is negative and highly statistically significant, while the average number of years of schooling is no longer significant.²⁵ These changes can be related to the fact that the hypotheses that we introduced about the migrants are at odds with the observed positive selection on education within the household, evidenced by Table 2. Clearly, these changes in $\hat{f}(\mathbf{x})$ have an impact on the composition of the control group, and on the estimated ATET.

This becomes apparent from Table 5, where the receipt of remittances is estimated to reduce the share of poor households among recipients between 17.1 and 18.6 percentage points with the bias-adjusted specification of the ATET. These figures correspond to a 57.2-59.2 percent fall in the incidence of poverty,²⁶ well above the 20.8 percent decline that represented the highest estimated effect obtained when migration represents the treatment variable of interest.

The Mantel and Haenszel (1959) bounds reveal that an unobserved factor that could *double* the relative probability of selection into treatment for observationally identical households would not suffice to explain the estimated effect of remittances on poverty. Hence, Table 5 suggests that remittances have a large and highly significant effect on poverty, which is *seemingly* more robust than the effects reported in Table 4 to a possible non-random selection on unobservables. Nevertheless, the larger values of the Mantel and Haenszel (1959) bounds are due to the reliance on a shorter recall period for remittances, as discussed below in Section 5.3.2, and the likelihood of a positive selection on unobservables substantially increases because of the introduction of hypotheses on the characteristics of the migrants.

5.3 Exploring the difference in the estimates

What can explain the contrast between these estimates, which could provide support to an optimistic view on the poverty-reduction potential of the recent wave of Ecuadorian migration, and the significantly lower effect that we obtained when focusing on migrant households? There are three main factors that can account for this difference,²⁷ namely (i) the substantial share of migrant households that do not receive remittances, (ii) the different

recall periods, and (iii) the introduction of hypotheses on the unreported characteristics of the migrants.

5.3.1 Non-recipient migrant households

As discussed in Section 4, nearly 30 percent of migrant households do not report to have received any transfer from their migrants in the 12 months before the survey. When the treatment is defined as the receipt of remittances, non recipient migrant households are excluded from the group of treated households and this can, in turn, magnify the size of the estimated ATET. We follow two different approaches, which reduce the share of non recipient in the treated group, to gauge the relevance of the difference in the definition of the treatment in accounting for the differences in the ATET reported in Tables 4 and 5.

First, we re-define the treatment z as having at least a member who migrated between 1998 and 2005 *and* receiving remittances over the longer 12-month recall period, and this reduces the number of treated households to 587.²⁸ The estimation of the propensity score is based on the reported individual characteristics of the migrants, as signaled in the third data column in Table 3. The estimated coefficients for the covariates are closer to those obtained in our benchmark specification, with education increasing the probability of exposure to the treatment. Table 6 reports the ATET: migration and the receipt of remittances reduce the incidence of poverty among treated households between 6.4 and 9.5 percentage points, which correspond to a decline in the poverty headcount ratio between 23.4 and 31.3 percent. The estimated effects are more robust to departures from the hypothesis of selection on observables than those in our preferred specification in Table 4.

Second, we defined z as having at least one migrant member who migrated between 1998 and 2003, and we drop from the sample the households with their first migration episode in the two years before the survey where the share of non recipient stands at 54.4 percent.²⁹ The fourth data column in Table 3 reports the results of the estimation of $\hat{f}(\mathbf{x})$ on this restricted sample, and Table 7 presents the ensuing estimates of the ATET. The bias-adjusted estimated ATET ranges between -5.4 and -7.8 percentage points when $n \geq 3$, suggesting that the migration episodes that occurred between 1998 and 2003 reduce the incidence of poverty among migrant households between 20.3 and 26.9 percent, an effect that is larger than in our benchmark specification. This larger effect is consistent with the expectation that, at least initially, the time elapsed since migration increases the likelihood

that the migrant sends remittances back home.

The non-negligible share of migrant households that do not receive remittances over the 12-month recall period thus contributes to explain the different reduction in the incidence of poverty that we find when we define migration or the receipt of remittances as the treatment of interest, but it falls short of accounting for the whole difference.

5.3.2 Different recall periods for remittances

When we focus on migrant households, the ENEMDU 2005 provides information on the remittances received over a period of 12 months, while the focus on recipient households forces us to rely on the amount of remittances reported just for the month before the survey. The shorter recall period can, as discussed in Section 4, induce an *overestimation* of the income from remittances for recipient households, whenever transfers do not occur on a regular monthly basis.

The average amount of remittances received in November 2005 by recipient households stands at \$261.34, significantly above the average monthly amount of remittances received by migrant households over the previous 12 months. Migrant recipient households receive a monthly average amount of remittances equal to \$195.80. This implies that the average amount of remittances measured over the shorter recall period exceeds by 33.5 percent the average monthly amount measured over the recall period of one year.

The *overestimation* in total household income for recipient households induces an *underestimation* in the observed incidence of poverty among recipient households, which Section 5.2 signaled to stand at 12.8 percent, well below the corresponding figure for migrant households. This, in turn, has a direct implication with respect to the estimated ATET, which depends, as evidenced in (5), linearly on the observed poverty status y_{i1} of treated households. Any underestimation of the incidence of poverty among recipient households leads, one to one, to an overestimation of the ATET, and it also increases the Mantel and Haenszel (1959) bounds, whose value is a monotonically increasing function of the share of non-poor treated households (Becker and Caliendo, 2007).

Furthermore, the probability of receiving remittances in the month before the survey is clearly increasing with the frequency with which households receive transfers from their migrants; hence, a shorter recall period for remittances leads to the inclusion in the group of treated of the households that receive a larger number of transfers per year. If the number

of transfers is positively correlated with their aggregate amount, then the group of treated is likely to under-represent the recipient households that receive lower amount of remittances, and this can also induce an upward bias in the estimated effect on poverty.

The empirical relevance of these arguments can be assessed if we define the treatment as having at least one migrant member between 1998 and 2005 *and* having received remittances over the one-month recall period. Such a definition reduces the size of the group of treated to 377 households, with an incidence of poverty that stands at 7.8 percent. This figure is 13.8 percentage points below the one recorded for recipient households when remittances are reported over the 12-month recall period, consistently with the underestimation of the incidence of poverty among recipient households that is induced by the reliance on a shorter recall period to measure a sporadic transfer.

The fifth data column in Table 3 reports the results of the estimation of $\hat{f}(\mathbf{x})$ under this definition of the treatment, and Table 8 presents the corresponding ATET. The bias-adjusted ATET reveals a reduction in the incidence of poverty between 16.0 and 19.6 percentage points, an effect that is significantly larger than the 6.4-9.5 percentage points reduction estimated when remittances are measured over the longer 12-month recall period (see Table 6). Furthermore, the estimated effect on poverty appears to be extremely robust to possible departures from the identifying assumption, as an unobservable factor that influences the probability of selection into treatment by a factor of *four* would not suffice to bring the ATET to zero.

These results entail that the length of the recall period over which remittances are recorded plays a key role in the explanation of the divergence in the results between our preferred approach, which focuses on migration, and the one that defines the receipt of remittances as the treatment of interest.

5.3.3 The hypotheses on the characteristics of the migrants

Household-level data on the receipt of remittances is rarely matched by information on the individual characteristics of the migrant who transfers resources to recipient households. As discussed in Section 3.1.1, the lack this information poses a threat to identification, because some relevant household characteristics become endogenous to migration, and this threat can be mitigated, but not fully addressed, by the introduction of assumptions on the (unknown) characteristics of the migrants.

The availability of individual information on absent members for migrant households gives us the opportunity of assessing the accuracy of the hypotheses. Table 1 evidences that migrant households have on average 1.35 migrant members and Table 1 signals that recent migration flows are gender-balanced, while our estimates in Section 5.2 have been based on the assumption that each recipient household only had one male migrant. Furthermore, and possibly more importantly, Table 2 also reveals that migrants are positively selected on education within each household, and this contrasts with the assumption that migrants have the same level of education as non-migrant members that we retained from Acosta *et al.* (2008).

How does the discrepancy between the observed characteristics of the migrants and the hypotheses that we adopted influence our estimates? To provide an answer to this question, we re-estimated the effect of migration on poverty disregarding the reported data on migrants and introducing the same assumptions as in Acosta *et al.* (2008). The results are reported in the sixth data column of Table 3 and in Table 9. The estimated coefficients for the education variables are in line with those reported in specification (2), as households with college education have a lower estimated propensity $\hat{f}(\mathbf{x})$ to be exposed to the treatment. The bias-adjusted estimation of the ATET reported in Table 9 reveal that migration reduces the incidence of poverty among migrant households between 4.9 and 7.8 percentage points, with the larger effect corresponding to a 27.2 percent reduction in the poverty headcount ratio. This is in line with the prediction that a systematic error in the measurement of some elements of \mathbf{x} for threatened households determines a bias in the estimated effect on poverty (Lechner, 2008).

We have provided evidence that points (i)-(iii) above contribute to explain the difference in the results obtained when focusing on migrant or on recipient households, with the length of the recall period for remittances being the single most relevant factor. The analytical choice of relying on the receipt of remittances to define the treatment of interest, which is often data-driven, produces estimates that are not, in our case, informative about the direct influence of international migration on poverty.

6 Concluding remarks

Our analysis reveals that the wave of migration that was triggered by the late-1990s economic crisis in Ecuador has induced a decline in the incidence of poverty among migrant households, that is estimated between 17.4 and 20.8 percent and which might also reflect a positive selection on unobservables. The availability of data on migrants and the measurement of remittances over a 12-month recall period proved to be critical in our analysis. The standard, and less data-demanding, choice to focus on the receipt of remittances as the treatment of interest would have produced a significantly larger estimated effect on poverty. The substantial share of non recipient migrant households only partly explains the difference between the two estimates, which is also driven by the shorter recall period for remittances and by the introduction of hypotheses on the characteristics of migrant members. The high migration costs that most would-be migrants faced at the end of the 1990s (Bertoli *et al.*, 2013) probably contributed to limit the direct poverty-reduction potential of the Ecuadorian exodus, as they hindered poor households from sending one of their members abroad.

Notes

¹The expression “migrant household” is used throughout this paper to denote a household that resides at origin and that has sent at least one of its members abroad.

²See Adams (2011) for a recent survey of the analytical challenges posed by the use of household-level data to analyse the effects of remittances on migrant-sending countries.

³The share of households with at least one migrant that do not receive remittances stands, for instance, at 41 percent for Nicaragua in Barham and Boucher (1998) and at 37 percent for Guyana in Agarwal and Horowitz (2002).

⁴Notice that this analysis is *not* meant to isolate the effect of remittances on poverty, opposed to a distinct effect of migration.

⁵Caliendo and Kopeinig (2008) provide an excellent survey of the analytical choices involved in the implementation of this estimation method.

⁶The availability of data on migrants allows us to fully account for the migration-induced variation in household-size, thus avoiding the risk, which is pointed out by Schiff (2008), of underestimating the effect of migration on poverty.

⁷An alternative approach to reduce the concerns about endogeneity is to introduce explicit assumptions about the migrant members, when these are unobserved; for instance, Acosta *et al.* (2008) follow Rodriguez (1998), assuming that “remittances are sent by an adult male family member, who has the average years of education of other adults in the household” (p. 99).

⁸All the results presented in Section 5 are robust to the exclusion from the sample of the households residing in these two provinces.

⁹The limited time elapsed since the treatment also mitigates the concern about the direct and opposite effects of migration on the number of dependent members in the household, due to the reduction in the opportunities for sexual intercourse between the migrant and the spouse left behind and to the improved chances of survival of older members due to a migration-induced increase in consumption.

¹⁰See, for instance, Acosta *et al.* (2006, 2008) and Calero *et al.* (2009) for analyses on Ecuadorian data.

¹¹Specifically, the asset index, which is built by Bertoli (2010) only on the basis of the assets that are “more likely to reflect past savings” (Acosta, 2011, p. 919), is an increasing function of the years passed since migration; this might reflect either the positive effect of remittances or the depletion of household assets to cover the monetary costs of migration, or both.

¹²This choice is in line with McKenzie *et al.* (2010), who observe that “among the other non-experimental methods, difference in-differences and propensity score matching with bias-adjustment work best” (p. 942) when estimating the income gains from migration.

¹³See Caliendo and Kopeinig (2008) for an overview of the alternative approaches to test the sensitivity of the estimates to the existence of confounders.

¹⁴The exclusion of recipient households with no migrants is motivated by the idea that a large share of these households could be actually mis-reporting with respect to the existence of a migrant, although this group also certainly includes recipient households belonging to the extended family of the migrants; the

results of our analysis are unaffected by this sample selection criterion. Notice that the impossibility to identify with certainty the recipient households that actually have no migrants and the availability for them of data on remittances only on the shorter one-month recall period hinder any analysis of the effects of remittances on their poverty status.

¹⁵The poverty line was set at \$56.60 per month, which corresponds to \$3.77 per day at purchasing power parity terms (World Bank, 2012).

¹⁶Early contributions to the literature (Gustafsson and Makonnen, 1993; Leliveld, 1997) relied on the comparison between these two figures to assess the impact of migration and remittances on poverty.

¹⁷If the migrant was the main breadwinner within the household, than the income per capita of the stayers falls after migration.

¹⁸Our results are robust to the adoption of the \$2 a day poverty line, in purchasing power parity terms, and to the reliance on an equivalence scale to define poverty on the basis of income per adult equivalent; the estimates are available from the authors upon request.

¹⁹The estimates presented in this section are robust to defining the treatment on the basis of migration to Spain only, a choice that greatly limits the concerns about a better within-county connection to migration networks for treated than for non-treated households, given the limited to non-existent network of Ecuadorians in Spain before the late 1990s (Bertoli *et al.*, 2011).

²⁰We retain the same specification of the vector of covariates across the six specifications presented in Table 3, as changes in the set of covariates would blur the interpretation of the differences in the estimated ATET obtained with different definitions of the treatment z .

²¹We also include dummies for the 21 Ecuadorian in-land provinces, to control for residual unobservable factors that can simultaneously influence poverty and migration at the provincial level.

²²Adding just the gender of the household head, as in Adams and Cuecuecha (2013), to the vector of 28 covariates suffices to increase the pseudo- R^2 by 40 percent, from 0.124 to 0.174. Still, household headship is endogenous with respect to migration as it is defined only among non-migrant members, and the significantly higher share of female-headed households among migrant (34.8 percent) than among non-migrant households (15.9 percent) is likely to have been determined by the migration of the former male household head.

²³The treatment is estimated to *increase* the incidence of poverty between 7.8 and 8.7 percentage points if we define the poverty status on the basis of earnings from domestic sources only, thus excluding remittances.

²⁴Our estimates are robust to the exclusion of non-migrant recipient households from the sample.

²⁵We can also observe that the dummy variable for residence in rural areas is now negative and significant.

²⁶These figures are close to those obtained for Ecuador by Acosta *et al.* (2007), which estimate a 51.6 and 52.4 percent decline with a two-stage Heckman procedure when poverty is defined according to the national extreme poverty and the \$2 a day poverty lines respectively, and remittances are measured over a one-month recall period using a 2004 round of the ENEMDU survey.

²⁷A fourth factor could be represented by the receipt of remittances by non-migrant households; as discussed in Section 4, we dropped from the sample the households with no migrants that received remittances in November 2005, and this sample selection criterion deprives this additional factor of any empirical relevance in our case.

²⁸We exclude from the sample migrant non-recipient households; the estimates, which are available from the authors upon request, are robust to their inclusion in the sample.

²⁹The estimates are robust to the exclusion of all migrant households with any migration episode in the two years before the survey, or in 2005 alone, as all these different sample selection criteria determine an increase in the ATET; results are available from the authors upon request.

Table 1: Descriptive statistics

<i>Variables</i>	Households		
	<i>Non migrant</i>	<i>Migrant</i>	<i>All</i>
Monthly income per capita, \$	123.34 (174.56)	150.91 (159.34)	124.83 (173.88)
Monthly non-remittance income per capita, \$	123.34 (174.56)	117.75 (148.96)	123.04 (173.28)
Monthly total remittances, \$	0.00 (0.00)	138.70 (226.02)	7.51 (61.20)
Poor ^a	32.02 (46.66)	20.89 (40.68)	31.42 (46.42)
Poor, ^a non-remittance income	32.02 (46.66)	36.12 (48.06)	32.24 (46.74)
Migrants	0.00 (0.00)	1.35 (0.79)	0.07 (0.36)
Resident in rural areas ^a	35.19 (47.76)	26.28 (44.04)	34.71 (47.60)
Network ^a	0.78 (1.75)	1.22 (2.83)	0.80 (1.83)
Indigenous ^a	12.76 (33.37)	12.97 (33.62)	12.78 (33.78)
Household size	5.23 (2.40)	6.71 (2.88)	5.31 (2.45)
Working age members	3.11 (1.61)	4.41 (1.78)	3.18 (1.64)
Dependency ratio	0.38 (0.24)	0.31 (0.19)	0.38 (0.24)
Female share	0.50 (0.22)	0.53 (0.21)	0.50 (0.22)
College ^a	12.95 (33.57)	25.02 (43.34)	13.60 (34.28)
Years of schooling	8.37 (4.06)	9.60 (3.31)	8.44 (4.03)
Observations	15,257	832	16,089

Notes: ^a percent; standard deviations in parenthesis; sampling weights used to compute all descriptive statistics; networks represents the county-level share of households with at least one migrant to the US before 1998; the dependency ratio is computed as the ration between dependent members and household size; years of schooling measured on working age members; college is a dummy variable signaling whether at least one household member has completed college education; the poverty line stands at \$56.60 per capita.
