Abstract: Depending both on structure and properties of the starting carbonaceous material, and on the fluorination conditions, fluorine can bond to carbon fibres in various ways. This review aims to investigate the versatility of the C-F bonding and its influence on the fibre properties. Morphology and surface properties, such as diameter, Scanning Electron Microscopy observations, specific surface area, wettability and surface acidity are discussed according to the fluorine content and the fluorination route. Structural and bulk properties of fluorinated carbon fibres, regarding Raman spectroscopy, X-ray diffraction analysis, electrical and mechanical properties, and bonding with polymers are also studied. 114 papers are reviewed in order to both extract general trends on those characteristics and highlight applications as fillers in composites and sensitive materials in gas sensing.

Keywords: Fluorination; Oxyfluorination; Carbon fibers; Surface and Bulk Properties; XPS; Wettability.

1 Introduction

Carbon fibres are known to be high-strength materials, which offer one of the highest Young moduli (up to 760 GPa) and strengths (up to 5.65 GPa) amongst reinforcing fibres. They are often used as reinforcement materials for composites in several fields such as aerospace, nuclear and transport [1,2]. However, in order to exploit the outstanding mechanical properties of carbon fibres in composites, the adhesion at the interface between the fibres, which support the stress, and the matrix, which distributes it, has to be optimised [3]. As carbon fibres are known to be highly inert materials due to their graphitic structure [4], their surface has to be functionalised to achieve maximal stress-transfer properties.

Numerous ways of functionalisation have already been successfully developed in literature for carbon fibres. The most known are based on oxidative treatments [5–7], plasma treatments [8,9], electrografting [10,11], or chemical grafting of oxygenated [12] or nitrogenated [4,13–15] species. Other innovative and promising methods exist, such as microwave irradiation [16,17], metal oxide coating [18,19], or bio-inspired functionalisation [20,21]. Independently of the retained method, similar trends are observed: fibre tensile properties are maintained, while fibre wetting with resin, interfacial shear strength (IFSS), and fibre-based composite tensile strength are improved.

Another well-known way to functionalise carbonaceous materials is fluorination. This treatment offers interesting advantages over other surface modification methods:

- Direct fluorination is a dry process, meaning that it does not require use and storage of often toxic solvents. Moreover, optimised fluorination conditions lead to a low ecological footprint treatment, without human contact with the reactant [22].
- Safe methods exist to neutralise residual F_2 and fluorinated end-products in the fluorination reactor [23], e.g. soda lime trap.
- Fluorination requires a strict control of the experimental conditions. It is both a difficulty (as discussed later) and an advantage, because it allows to reach controllable and repeatable properties on fluorinated materials.
- The versatility of the C-F bond nature, that will be discussed later too, is also a difficulty and an advantage at the same time: it allows to reach an extraordinary diversity of properties for fluorinated materials, but requires a good comprehension and control of the experimental conditions and starting material.
- Most fluorination processes may be performed at the industrial scale, as proved by the fluorination of car tanks [24].
- If fluorination occurs at room temperature (RT), it is a low energy consuming reaction. Independently of the reaction temperature, as fluorine is highly reactive, it is a quick surface modification method.

Fluorinated carbons own highly interesting properties, such as chemical stability, tunable bandgap, good thermal conductivity, or super-hydrophobicity [25]. However, the comprehension of the phenomena at stake during the fluorination treatment can be complex, due to both the versatility of the C-F bond nature [26] and the large panel of fibre precursor properties, such as crystalline order, specific surface area, texture, or morphology [27]. Both the structure and properties of starting material, as well as the chosen fluorination conditions, for instance temperature, pressure or duration, can explain this versatility [28], which will be highlighted all along this review. Moreover, the presence of oxygen atoms also plays a key role. The properties conferred by fluorination to carbon fibres, such as wettability, structural evolution or mechanical properties, will indeed depend of the C-F bond nature, which can be

evidenced using either X-ray photoelectron spectrometry (XPS) or solid state Nuclear Magnetic Resonance considering ^{19}F and/or ^{13}C nuclei [29,30].

As a matter of fact, this review aims to sum up the main findings that have been reported in works about the fluorination and oxyfluorination of carbon fibres. How fluorine atoms graft to the fibre surface will be investigated first, before going further on the study of surface and bulk properties induced by (oxy)fluorination treatments.

2 Fluorination and oxyfluorination routes

The grafting of fluorine atoms onto the surface of the fibres or into their bulk requires the use of a strong oxidant such as molecular fluorine (F_2), for which the reactivity may be either decreased by dilution with an inert gas (e.g., He , N_2) or increased in gaseous mixture with HF or O_2 . The reactive gas or its mixture may be introduced either in dynamic mode with a continuous flux in an opened reactor (always passivated with NiF_2 coating and linked to a trap to remove the excess of F_2 and side products such as CF_4 , C_2F_6 , HF , OF_2 according to the chemical composition of the precursor) or in a static mode. In this latter case, a defined amount of gas is introduced in a closed passivated reactor (the trap is then useful at the end of the process during the flush with an inert gas). The reaction kinetics differ according to the fluorination mode [31]; static fluorination provides the non-decomposition of the carbonaceous matrix during fluorination.

The fibres exhibit the same trends than graphite regarding their reactivity towards molecular fluorine. The higher the graphitization degree, the higher the fluorination temperature [32]. When the specific surface area is increased, through a nanostructuration (e.g. nanofibres [33] or multiwalled carbon nanotubes, MWCNTs [34]), or porosity [35], the reactivity increases as well the risk of decomposition under F_2 atmosphere. It is important to note the risk of exfoliation when the reactive gas is introduced at high temperature with high reactive gas flux. The case of nanofibres perfectly evidences such a phenomenon [36]. When the carbon lattice exhibits a curvature, the reactivity towards F_2 increased; fullerenes and derivatives (nanotubes) may be fluorinated at low temperature and even at room temperature [37].

When only the surface must be fluorinated, reaction in fluorine-containing gas assisted by plasma is an alternative. For many years, this technique has been used in order to modify the surface properties of different materials. Indeed, if first employed for changing the surface properties (hydrophobicity, adhesion, friction, bio-compatibilization, etc.) of different polymers [38], plasmas were quickly used to treat carbon fibres during the 80's [39–41]. The main use of these fibres is polymer matrix reinforcement for the preparation of composites. Thereby, all of these treatments were aiming at preparing the surface of the fibres in order to improve the interface properties between both components of these materials. Treatment are therefore mainly devoted to cleaning the surface by removing the impurities, creating a surface roughness to improve the mechanical anchorage of the resin, or the chemical grafting on the fibre surface to create chemical interactions between the fibres and the matrix [42]. Thereby, as an example, some researchers have demonstrated that plasma treatment of carbon fibres allows the surface roughness of fibres to be increased and, consequently, enhances their adhesion with polymers [43–45]. Some others have carried out experimentations that aim at grafting chemical groups at the outmost surface of carbon fibres. Most of the time, oxygen-based plasma were carried out in order to graft oxygen groups (COOH , C-OH , C=O) at the fibre surface, especially to improve the carbon fibres/epoxy matrix interface *via* the addition of these polar groups [39,46–48].

On the other hand, if fluorinated plasmas were first developed for micro-electronic etching [49], they were quickly employed to modify surface properties of various carbon compounds (graphite, diamond, etc.) [50,51], in order to confer to the latter ones surface properties of fluorocompounds (hydrophobicity, corrosion resistance, low dynamic friction, high scratch resistance, etc.) without modification of the bulk properties in the same way than direct fluorination. Typical used fluorinating agents are SF₆, NF₃, CF₄, CHF₃, C₂F₆, C₃F₆ and C₄F₈ gases [52,53]. In the reactor, electrons which compose the plasma will acquire enough energy to initiate dissociation, ionization or attachment reactions with the molecule radicals or atoms [49], which are very effective reactions on carbon compounds. However, it is only in 1987 that Loh *et al.* [40] published one of the first papers on carbon fibre fluorination in plasma, using CF₄-He and F₂-He plasmas at various flow rates to modify the surface properties of these compounds [40]. Results demonstrated covalent grafting of fluorine atoms at the outmost surface of carbon fibres by forming a chemical structure similar to that of graphite fluoride. Thereafter, it would be necessary to wait Ho *et al.* works to really discover the possibilities brought by fluorination treatments in the composite field. Indeed, by using a N₂ + CHClF₂ gas mixture atmospheric plasma jet treatment, the authors succeeded to increase the water contact angle of fibres from 55° to 103° but with the appearance of pinholes on the fibres surface [54]. This modification allowed to increase the compatibility of these fibres with polyvinylidene fluoride (PVDF) matrix. Indeed, results showed that the contact angle between treated fibres and melt PVDF is reduced, interfacial shear strength is increased, and this without modifying the bulk mechanical properties of the fibres [55–57]. The interest of fluorinated plasma treatments for composite applications is well highlighted by this last example.

RT-pulsed fluorination has been developed for materials that cannot be fluorinated using direct fluorination (e.g. carbon aerogels, CA), due to their high specific surface areas or high sp³ hybridised carbon amounts, with the objective to create a fluorination method less expensive than controlled fluorination [35]. It is similar to static fluorination, although the pre-calculated amount of fluorine is not introduced at once, but in several small injections, allowing to observe the fluorine absorption and reaction kinetics, divided into 4 steps according to the authors: after vacuum and fluorine first injection (step 1), fluorine rapidly reacts with CA, leading to a purification of the carbon lattice and fluorine grafting on the surface vacant sites of the carbon (step 2). After several injections, the fluorine absorption by CA is slower, because vacant sites become rarer (step 3), and the CA ends being saturated with fluorine, thus stopping the reaction (step 4). RT-pulsed fluorination avoids decomposition or generation of structural defects.

For both direct fluorination with F₂ or assisted with plasma, the presence of heteroatoms (e.g. O, H or N) in the fluorinating agent plays a key role in the reaction mechanisms because they are involved in functional groups with high reactivity towards fluorinated species. These heteroatoms allow to reach high fluorine amounts [58–60], because the intercalation of fluorine is enhanced by the presence of Lewis acids (O₂ or HF): they balance the weak orientational polarizability of fluorine, by forming mobile anions, and allowing fluorine to intercalate into graphite as the mobile anion [59]. Moreover, the formation of C-F covalent bonds and hydroxide radicals makes the surface more basic, which hinders the fluorination reaction to go further. By acidifying the fibre surface, Lewis acids curb this basifying effect [59].

Another advantage of oxyfluorination, linked to the increased reactivity of fluorine in the presence of Lewis acids, is that treatments appear to be short with relatively low pressures and temperatures, with durations as 3-10 min [3,61–63], 30-60 min [64–66] or 120 min [59], while fluorinations under pure fluorine generally last from 15 min [67] to several hours

[58,60] or days [60,68], under high temperatures for short durations. As shown by the works cited above about oxyfluorination, despite durations are short, this treatment leads to high-fluorine and relatively low-oxygen surface contents.

Another promising fluorination route is the fibre sizing one. It is to note that although most commercial carbon fibres are sized, both to protect them during handling and textile processing [69] and to improve their compatibility with polymer matrices [70,71], they are often desized before fluorination [54,67,72] or acquired unsized [3,59,62,63]. If they are fluorinated with their sizing, its influence is neglected as it burns under strong fluorination conditions [61,67,72]. However, under mild fluorination conditions, it is possible to achieve a sizing perfluorination, as shown on carbon [73] and flax [22] fibres. This perfluorination has conferred interesting properties, e.g. increased hydrophobicity, without modifying the fibre structure and bulk properties, as it will be studied later.

The fluorination mechanism on Bisphenol A diglycidyl ether (DGEBA) as a sizing agent has been studied in [22], where a wide variety of potential perfluorinated and overfluorinated groups derived from DGEBA have been evidenced. Knowing that i) the oxirane ring of DGEBA has an important internal tension, ii) the aromatic rings are highly reactive, and iii) the C_6F_{10} ring is stable, some fluorinated groups are more likely to form than others. Moreover, the authors have established preferential scission sites on perfluorinated DGEBA, underlining the DGEBA reactivity under fluorine treatment [22].

More generally, fluorination of polymer converts CH_x groups in CF , CF_2 and CHF_y groups [74,75], with CF_2 and CF_3 being characteristic of respectively perfluorination and C-C skeleton breaking, while $C=C$ bonds are saturated with fluorine, as extensively proved in Kharithonov's studies on polymer fluorination [23,24,76–80].

Other fluorination routes exist, e.g. atomic and controlled fluorination or sub-fluorination. Their specificities and mechanisms will be detailed in section 3.2.2. Figure 1 summarizes the most usual routes and their main parameters.

Figure 1: The fluorination routes for carbon fibres and their main parameters (some figures were reprinted from [56], with permission from Elsevier, and from [81])

To conclude this part about the (oxy)fluorination routes, the main experimental difficulties that can be met when fluorinating carbon fibres, beyond fluorine intrinsic hazards, are cited thereafter:

- Exfoliation, mentioned above, happens when the reactive gas is introduced at high temperature with high reactive gas flux. If high temperatures are required for reaction, it can be avoided by setting a moderate reactive gas flux.
- High gas flux may also, if fibres (or powder) are too close to the gas entry, pulverise the carbon material into the whole reactor, thus polluting it.
- Direct fluorination of carbon materials being highly exothermic, a strict control of the fluorination duration (second by second) and gas flows (accuracy deviation below 1 mL/min) are necessary to obtain materials with similar fluorination rates.
- Industrial carbon fibres are often commercialised as fabric rolls made of carbon fibre bundles (e.g. 12 000 fibres per bundle). If the post-fluorination application needs the fibres to be long (e.g. 40 cm), as bundles are poorly foldable, this means that the fluorination reactor has to be long enough to fluorinate the whole fibre length homogeneously. Moreover, if the reactor has only one gas entry, the closest portion of carbon fibre fabric might be more intensely fluorinated than the other ones, raising the question of fluorine introduction into the reactor. This problem might be solved by innovative fluorination processes, such as in [56], where the authors have achieved continuous fibre fluorination.
- Another problem, directly coming from the reactor size required for long carbon fibre fluorination, is the temperature one: if small reactors can be easily and homogeneously heated at important temperatures, with real temperature close to the setpoint one, this is more complex with voluminous reactors, which may have important offsets between real and setpoint temperatures. Before fluorination, this offset should be measured using a thermocouple. Concerning the temperature homogeneity, it can be improved by using a double envelope reactor, but still needs time to be achieved.
- Standard industrial carbon fibres are usually sized, the sizing being a thin polymeric coating. It is often an epoxy resin, for further use with epoxy matrix [82] or more specifically diglycidyl ethers, the most used matrices for composite applications [83]. If fibres are not desized before fluorination and that fluorination temperatures are low, sizing fluorination takes place [73]. Unless the latter phenomenon is sought, the fluorination temperature and/or duration should be important enough to fluorinate the carbon fibre and completely destroy the sizing.

3 Fluorine content and bonding

The differences in surface element content and bonding between pristine and (oxy)fluorinated carbon fibres reported in literature will be first discussed. These differences were notably highlighted thanks to elemental analysis (EA), chemical analysis (CA), weight uptake, chemical titration, and XPS analysis. The latter technique allows to know the outmost surface (< 10 nm) composition of a sample and the bond nature of the detected elements.

3.1 Study of the carbon fibre surface before the (oxy)fluorination treatment

Elemental and XPS analysis processed before (oxy)fluorination give information about the initial carbon fibre surface composition. Table 1 computes the compositions reported in literature.

Table 1: Reported compositions of carbon fibre precursors using XPS and CA

Reference	C surface content (%)	O surface content (%)	N surface content (%)	Si surface content (%)	O/C ratio
[68]	100	-	-	-	-

[60,68]	83	14	3	-	0.17
[67] ¹	82.1	2.5	14.1	-	0.03
[54]	75.4	18	1.2	5.4	0.24
[66]	55	45	-	-	0.82

Overall, fibre surfaces appear to be mostly constituted of carbon. Heteroatoms like oxygen, nitrogen or silicon are sometimes present and are considered like impurities, which can amongst others come from the fibre handling [54]. One could assume that these heteroatoms could come from the sizing, but some of the fibres with the highest O/C ratio were unsized [3,62,63] or desized [54], which excludes the hypothesis with the sizing.

It is to note that the most carbonaceous surfaces, reported in [68], correspond to high-temperature treated (HTT) carbon fibres. This graphitisation at 3000°C has completely removed the 11% of heteroatoms (bold text in Table 1), and has only left carbon. In that respect, most of the commercially available carbon fibres studied here have an 80-96% carbon surface content, a 2.5-14% oxygen surface content, a nitrogen surface content under 5%, and an O/C ratio under 0.20.

It is now possible to study more precisely how the carbon atoms and heteroatoms are bonded together on the surface of non-(oxy)fluorinated fibres, thanks to XPS. This technic indeed allows to determine the nature of the surface atomic bonds, thanks to the study of the C 1s and O 1s binding energies and their deconvolution in several peaks, which are characteristic of a specific bonding. Table 2 and Table 3 summarize binding energies of common functional groups in the C 1s and O 1s areas, while Table 4 computes the calculated amounts of each bond on carbon fibre surface according to literature.

Table 2: Binding energies (eV) of C 1s atomic bonds commonly found at carbon fibre surface

Reference	[84]	[85]	[86]	[87]	[88]	[89]
C=C	284.5	-	284.2	285.2	284.5	-
C-C	-	284.5	284.9	284.6	-	285
COH	286.0	285.9	285.5	286.7	285.6	286.6

C=O	287.4	287.3	287.7	-	288.2	288.1

¹ Values determined by CA

O-C=O	289.1	289.3	288.7	-	-	289.3
-------	-------	-------	-------	---	---	-------

Table 3: Binding energies (eV) of O 1s atomic bonds commonly found at carbon fibre surface

Reference	[84]	[90]	[91,92]	[93]	[94]
C=O	531.1	532.2	532.3	532.6	530.9
C-O	533.1	532.8	533.8	534.3	-
O=C-O	534.0	532.2	-	-	532
O=C-O-C		533.7	-	-	

Then, the XPS spectra are deconvoluted in several peaks according to these values. The comparison between the peak areas allows the amount of each type of bond to be estimated (Table 4).

Table 4: Reported relative contents (%) of various assignments for C 1s and O 1s cores using XPS on carbon fibre precursors

	Reference	[58,68]	[59]	[58]	[68]	[60,68]	[66]	[67]	[67]	[64]	[64,65]
C 1s	Graphitic C (%)	100	77.8	86.8	70	67	55	48.1	42.3	42	40
	COC COH (%) ²	-	11.8	13.2	21	33	25	44.1	38.8	34	16
	C=O (%)	-	10.4	-	9	-	20	7.9	18	24	31
	O-C=O (%)	-	-	-	-	-	-	-	-	-	13
	Undefined (%)	-	-	-	-	-	-	-	0.9	-	-
O 1s	C=O (%)	-	-	-	-	-	54	-	-	-	45
	CO (%)	-	-	-	-	-	46	-	-	-	29
	O-C=O (%)	-	-	-	-	-	-	-	-	-	26

The reported relative contents greatly differ depending on the study, but all fibre surfaces appear to be mainly constituted of graphitic carbon, and of ether, hydroxyl, carbonyl, and carboxyl groups. It is of primary importance to know more about the carbon fibres before their treatment because fluorination will focus preferentially on oxygenated groups [67] and sp² carbons [95].

3.2 Study of the (oxy)fluorinated carbon fibre surface

3.2.1 Surface atomic contents

As Table 1 and Table 4 have given an overview about the surface composition of the carbon fibre precursors, a compilation has been done on fluorinated and oxyfluorinated carbon fibres. For the surface atomic contents, this leads to Figure 2 and

Table 5, where APF stands for “Atmospheric Plasma Fluorination”.

² For [60,68], C=N is also included in this %

Figure 2: Relative surface atomic contents of fluorinated carbon fibres according to literature, using XPS and EA

Table 5: Correspondence between the sample numbers of Figure 2 and the way samples are referred in literature

As it can be seen on Figure 2, the surface composition of carbon fibres is highly disparate, even from one sample to another within the same study. The surfaces are mostly constituted of carbon and fluorine: the minimum surface content of {carbon + fluorine} is 80% and is reached on fibres moving through a fluorinated atmospheric plasma (sample n°28 in Figure 2). The fluorine content range is large, from 1.1-1.6% up to 55-65%, depending on the fluorination treatment.

On one hand, atmospheric plasma fluorination leads to the lowest fluorine grafting (1.1-1.6%) [54]. A $\text{CHClF}_2\text{-N}_2$ mixture has been used to generate a plasma that fluorinates fibres for various durations (1 to 8 min). Even if the fluorine content is low, it can be noted that APF is intense enough to decrease the surface content of heteroatoms. Another study [56] using the APF of carbon fibres, with the same gas mixture, has led to surface fluorine amounts from 1.3% up to 4.9%: these amounts are slightly higher than in [54] and the chosen method offers an interesting processing advantage, as the fibres to be treated are not static anymore but moving through the plasma jet in a continuous process. But in both cases, it is to note that these contents remain low compared to the ones reached with more severe fluorination treatments.

On the other hand, the highest fluorine contents (55-65%) were reached in [67], by using direct fluorination with molecular fluorine F_2 (samples n°1-8 in Figure 2). The main parameter resulting in these fluorine contents appears to be the temperature. As a matter of fact, this study has involved the highest reported temperatures, i.e. 378°C, to the best of our knowledge, and it has led to the highest fluorine surface contents.

Other studies have reported samples with high fluorine amounts [58–60]. All of these samples (n°18, 21, 32, 39 and 40 of Figure 2) have a common characteristic: the reacting gas is not pure fluorine, but rather a $\text{F}_2\text{-HF}$ or $\text{F}_2\text{-O}_2$ mixture, which has been explained in 2. The importance of Lewis acids is highlighted by the fluorine content gap between samples n°37-38 (F_2 fluorination) and n°38-39 ($\text{F}_2\text{-O}_2$ oxyfluorination) of Figure 2: the first ones have 14-16% surface fluorine contents, while the second ones exhibit 60-65% surface fluorine contents [59].

The treatment duration also seems responsible for an increase of the fluorine surface content. This is highlighted by the fact that sample n°32 in Figure 2, which has been fluorinated for 9 days, has a higher fluorine surface content (41%) than samples n°30 and n°31 (18-21%),

which have been fluorinated for respectively 1 and 5 hours, with almost the same gaseous mixture and same pressure [60].

As we consider a heterogeneous gas/solid reaction, another parameter that could increase the fluorine surface amount is pressure, as highlighted by sample n°17 in Figure 2, which is the only high-fluorinated sample and has not been fluorinated with a Lewis acid. Two factors could then explain this high fluorine amount despite a pure F₂ fluorination: first, the fluorination of this sample has lasted for 6 hours. As seen just above, this could enhance the grafting of fluorine on the carbon fibre surface. Secondly, this sample has been fluorinated under high pressure (21-26 bars), which could increase the proportion of fluorine grafted.

To briefly talk about other chemical species at the surface of (oxy)fluorinated fibres, there are traces of nitrogen, from 0% up to 3.1% on sample n°26 of Figure 2 (continuous APF fibres). About oxygen, it can be found in various amounts, from 0% on sample n°40 (125°C oxyfluorination) up to 13.6% on sample n°23 (4 min APF fibres), according to Figure 2. It should be noted that oxyfluorination treatments are not especially leading to rich-oxygen surfaces, as the oxyfluorinations reported in Figure 2 lead to oxygen surface amounts from 0-0.5% (samples n°39-40, [59]) up to 10.1-11.3% (samples n°33-36, [3,62,63]).

3.2.2 C-F bonding at the carbon fibre surface and fluorination mechanisms

Now that the species present at the carbon fibre surface and their amounts have been specified, it is possible to discuss the nature of the chemical bonds between these atoms. To this end, XPS data from several studies have been summarized in Figure 3 and Table 6. Figure 4 and Table 7 gather XPS data that could not be included in Figure 3, because XPS peaks have been deconvoluted independently of each other.

But before studying the nature of these chemical bonds, the ways fluorine can graft to carbon will be briefly presented, in order to better understand the computed data.

First, fluorine can covalently bond to carbon, by breaking the double bonds of graphitic carbons and the conversion of carbon hybridization from sp² to sp³. This evolution from graphitic to tetravalent carbons with the fluorination treatment has already been reported many times in various studies on fluorinated carbon fibres [58,59,62,67,96], or more widely on fluorinated carbonaceous (nano)materials [95,97–101]. For ordered carbons, this sp² to sp³ conversion occurs under pure fluorine at high temperatures (process known as “direct fluorination”), at least 300°C [96], or more generally under strong fluorination conditions [58,61]. (CF)_n and (C₂F)_n structural types may be formed according to the temperature and duration. (C₂F)_n with FCCF/FCCF stacking sequence is an intermediate phase in the 350-500°C range whereas (CF)_n (FCF/FCF stacking) is formed at the highest temperatures up to 650°C [102]: the higher the temperature, the higher the fluorination level x ($x = \text{F:C}$, $0.5 < x < 1$) [103].

Another point of view consists to consider graphite fluorides as covalent graphite intercalation compounds with stage 1 and 2 for (CF)_n and (C₂F)_n, respectively. Purely covalent C-F bonds are then formed and are stable up to 500°C [96]. These covalent bonds are evidenced with XPS, through a peak at 689 eV [67].

Another possible kind of bonding between fluorine and carbon that can be observed through XPS is the intercalation of fluorine into the graphitic structure. It has been reported to occur at quite low temperatures (< 100°C) [62,96], when the gaseous mixture is composed of fluorine and fluorides, such as HF, ClF₃ or IF₅ [59,62,96,103]. When fluorination takes place with F₂, HF and another fluoride, it is described as “catalysed fluorination”. In this case, Guérin et al.

have highlighted that the fluoride choice influences the fluorination level, the latter one being related to the Lewis acidity of the fluoride and its interaction with HF [103]. They have also studied the post-fluorination mechanism of low temperature fluorinated graphite depending on the post-fluorination temperature: fluorine bonding can be weakly covalent with residual catalyst ($T < 400^{\circ}\text{C}$), increasingly covalent thanks to catalyst de-intercalation and fluorine amount increase ($400^{\circ}\text{C} < T < 550^{\circ}\text{C}$), or totally covalent, with less structural defects than directly-fluorinated graphite ($550^{\circ}\text{C} < T < 680^{\circ}\text{C}$).

Intercalation happens because the reaction between pure fluorine and carbon is kinetically limited at low temperatures: fluorine reacts with the surface carbon to form covalent C-F bonds, and prevents the fluorine progression deeper in the fibre bulk, and thus further fluorination [59]. In this case of intercalation, the sp^2 state of carbon, i.e. the planarity of graphene layers, is maintained: the fluorine only inserts into the graphitic structure as a graphite intercalation compound (GIC) and is linked to carbon through ionic ($x < 0.25$) or semi-covalent ($0.25 < x < 0.5$) bonds, i.e. with weakened covalence. GICs have the general formula C_xF , where $1.3 < x < 20$, and are unstable, even at low temperatures [59,62,96]. It has been reported that the more the fibres were graphitised, the more it was possible to intercalate fluorine in the layered pattern [61,68]. Another source for weakening of the covalence for C-F is the dilution of C-F bonds that results in neighbouring of C-F bonds with non-fluorinated sp^2 C atoms; an hyperconjugation takes place as proposed by Sato *et al.* [104].

In the case where perfluorinated groups (CF_2 , CF_3) are unwanted, fluorination can be done by using atomic fluorine $\text{F}^{\bullet}$ rather than molecular fluorine F_2 , thus favouring formation of C-F bonds [103]. This process, called “sub-fluorination” or “controlled fluorination”, can be achieved by thermal decomposition of a fluorinated compound called “fluorinating agent” (FA), e.g. XeF_2 or TbF_4 , which will release a controlled amount of atomic fluorine into the reactor. The recombination of two $\text{F}^{\bullet}$ in F_2 is avoided because the reaction between carbon and $\text{F}^{\bullet}$ is spontaneous [105]. Fluorination, whose kinetics depends on the FA decomposition rate [105], is then more progressive, less aggressive and homogenous, and leads to $(\text{CF})_n$ -type phase, i.e. highly-fluorinated phase, whatever the fluorination conditions. Few $(\text{C}_2\text{F})_n$ phase, CF_2 and CF_3 groups or dangling bonds are formed [103], while decomposition by overfluorination is avoided [105].

Fluorination mechanisms have also been studied at a microscopic level, notably by using Density Functional Theory (DFT) calculations on HF-catalysed fluorinated CNTs [106]. It has been found that non-regioselective (1,2) equatorial and (1,4) axial additions were thermodynamically favoured for flat multi-layered carbon materials, such as graphene, while curved materials such as CNT or locally-buckled graphene were rather fluorinated through (1,4) addition for low temperatures. For these materials, higher fluorination temperatures result in the migration of the fluorine atom to the (1,4) to the (1,2) position thanks to the formation of a hydrogen bond with the catalyst HF. These additions lead to the emergence of a pattern of fluorinated bands [105] constituted of C_4F or C_2F [106]. Zhang *et al.* [105] have shown that HF deposition in a pristine zone close to a fluorinated area will lead to its chemisorption with H atom facing a surface fluorine atom, while a HF molecule deposited in a non-fluorinated area will sit vertically above a carbon atom, the hydrogen atom being closer to the tube and will only be physisorbed, thus having a short lifetime: this explains why F_2 , which is catalysed by HF, is deposited near from the pre-existing fluorinated areas.

It is to note that the fluorination mechanism of graphite, previously studied, differs from the one of graphene and CNTs because fluorine can access to both sides of the carbon layer [106].

Concerning controlled fluorination, DFT calculations have shown that fluorine distribution at SWCNT surface is controlled by electronic repulsion between incoming fluorine atoms and carbon-bonded ones, thus explaining the controlled fluorinated homogeneity [105]. On the other hand, still using DFT, F₂ fluorination of SWCNTs has led to the formation of fluorine bands separated by pristine carbon parts by armchair axial addition of fluorine atoms [107], highlighting the higher homogeneity of controlled fluorination over direct fluorination.

In all cases (covalent bonding of (CF)_n and (C₂F)_n, hyperconjugation or formation of GICs, or (1,2) and (1,4) additions), the fluorine grafting on the surface of carbon materials drastically modifies some of their properties, such as tensile strength, interfacial and structural properties [58,59], as this will be discussed thereafter.

In Figure 3, the samples n°1-8 stand out from the other ones, notably because of the homogeneity of the formed chemical bonds between the samples. Fluorine is highly present at the surface of these samples, as at least 89% of the surface carbons are bonded to fluorine, through semi-covalent or covalent C-F bonds, or involved in CF₂ or CF₃ groups. The remaining carbons are mainly involved in C=C graphitic bonds, which is the main kind of bonds in non-fluorinated carbon fibres, as seen in Table 4. For these samples, considering the low relative content of remaining graphitic carbons, one could think that covalent grafting has been the main fluorination mechanism.

Still discussing about these samples, it can be outlined that the high content of CF₃ groups is the last stage of fluorination before the formation of gaseous species CF₄ and C₂F₆, which can lead to the removal of carbons by decomposition (combustion). This high amount of CF₃ groups highlights the fact that two antagonist mechanisms are competing during the fluorination treatment: the first one leads to the desired fluorination of the surface, while the

other one is the formation of the gaseous species cited above [67,72]. Temperature thus favours fluorination reaction, which can even lead to a degradation of the carbon fibre surface by forming CF_3 , CF_4 and C_2F_6 and partial exfoliation as discussed in section 2. Both decomposition and partial exfoliation may increase the roughness and even the porosity. This observation has already been made [58,59], and is strengthened by the fact that it has been proved that temperature was increasing the fluorination rate of polymer surfaces [23,24,76,79,80]: one could consider that a similar approach can be made on carbonaceous surfaces.

Another interesting point can be raised by observing the F 1s analysis provided by the different studies where fibres have been fluorinated (Figure 3): except for samples n°9-10, it can be noted that fluorine is more likely to form covalent C-F or CF_2 bonds than semi-ionic C-F bonds. This trend is observed on samples n°11-15 and n°22-24, despite the set of experimental conditions reported in Table 6 (low temperatures, gas mixes containing fluorides) that could let think that semi-covalent GICs would be preferentially formed than C-F and CF_2 covalent bonds.

However, for oxyfluorinated fibres (samples n°1-8 of Figure 4), this statement is not valid anymore: depending on the sample, the proportions of semi-covalent and covalent C-F bonds can be similar (e.g. samples n°2-3), or one type of bonding can be significantly more represented than the other one (e.g. samples n°7-8). Based on samples n°5-7 of Figure 4, it can be noted that an oxyfluorination duration of 30 min appears to be the most efficient time to covalently graft fluorine to the carbon fibres, as 10 min and 60 min durations lead to high amounts of semi-covalently bonded fluorine. Pressure also seems to increase the proportion of covalent fluorine: sample n°8 of Figure 4 has a slightly higher proportion of covalent C-F bonds than sample n°6, and the only difference between them is the F_2/O_2 pressure. Sample n°8 has indeed been oxyfluorinated at 80 kPa, while n°6 has been fluorinated at 5 kPa [64].

Figure 4 delivers an interesting information about the way oxygen atoms are bonded at the carbon fibre surface, and can be related to the oxyfluorination mechanism proposed in [59], which is reminded in Figure 5. Indeed, according to this mechanism, if fluorine and oxygen are introduced in similar amounts, all carbon radicals created by the attack of fluorine should become peroxide radicals thanks to oxygen, leading to high amounts of C-O and O-H bonds, detectable with XPS. This could explain why sample n°3 of Figure 4 has the highest amount of C-O/O-H bonds in its O 1s peak, as this sample has been oxyfluorinated with a 50/50 vol. % F_2/O_2 mixture [65].

Figure 5: A suggested mechanism of direct oxyfluorination of carbon fibres, adapted from [59], with permission from Elsevier

When fluorine is introduced in higher quantity than oxygen, one could think that oxygen would not be able to bond to all the carbon radicals created with fluorine. This could lead to a fibre with a high number of free radicals, which could recombine in carbonyl bonds during exposure to H_2O from ambient air; a high relative content of oxygen atoms implied in carbonyl bonds is then expected. This hypothesis could explain the high amount of $\text{C}=\text{O}$ bonds detected in the O 1s peak in sample n°4 of Figure 4, which has been oxyfluorinated with a 90%/10% F_2/O_2 mix [65]. The effect of radicals is thus of primary importance when the (oxy)fluorination is limited close to the surface.

On the other hand, when the oxygen represents the major part of the F_2/O_2 mixture, and as oxygen oxidation has been reported to introduce many carbonyls at the surface of carbon fibres [108], one could expect a high proportion of surface oxygen atoms implied in $\text{C}=\text{O}$ groups; the higher the oxygen content of the gas mixture, the higher the relative content of such groups. This could explain the high amount of carbonyl functionalities of samples n°1-2 of Figure 4, which have been oxyfluorinated using respectively a 10%/90% and a 30%/70% F_2/N_2 mix [65].

In conclusion of this section about the chemical composition on and close to the surface according to XPS data about (oxy)fluorinated carbon fibres, it has been highlighted that the pressure, the temperature and the nature of the gaseous mixture result in different chemical bonds, functional groups and fluorine content that act on surface properties. Two bonding mechanisms of fluorine may exist: covalent bonding under pure fluorine at high temperature, or formation of semi-covalent GICs in presence of gaseous fluoride, at relatively low temperatures ($< 100^\circ\text{C}$). Dilution of F atoms results also in weakened covalence.

4 Morphological and surface properties induced by fluorination

4.1 Diameter evolution

Studying the evolution of diameter is useful as it can give information about the (oxy)fluorination mechanisms. Slight decreases of the fibre diameter with (oxy)fluorination have already been reported, and attributed to both the partial etching of the fibres by fluorine and the formation of gaseous fluorocarbons [60,66]. Presence of amorphous parts on the surface may favour such an etching because of their higher reactivity towards fluorine in comparison with graphitized areas, as reported on nanofibres [33].

On the other hand, increase of the diameter has also been observed, and imputed to the diffusion of the fluorinating agent into the bulk of the fibre [67,109]. The interlayer distance is

much higher in $(\text{CF})_n$ (0.6 nm) and $(\text{C}_2\text{F})_n$ (0.9 nm) [110,111] than in graphitized carbons (about 0.34 nm) [112]. When both mechanisms occur, it has been highlighted that the decrease of diameter happens before the swelling [60].

4.2 SEM observations and specific surface area (SSA)

Like in the case of the diameter evolution where two physical phenomena occur, two opposite observations can be made on the surface of (oxy)fluorinated fibres using scanning electron microscopy (SEM). First, (oxy)fluorination can smooth the fibre surface, by attenuating the fibre striations [54,59]. (Oxy)fluorination can also roughen and damage the fibre surface, by removing weak-bonded surface layers of carbon [54,61,67]. Porous areas along the fibre axis have also been evidenced [61], as well as more pronounced striations and holes at the fibre surface [54,61]. Under APF, carbon sputtering has been reported too [54].

When (oxy)fluorination roughens the fibre surface, specific surface area (SSA from BET method) can either slightly increase (increase of 0.3-0.4 m²/g) and be linked to a tiny surface roughening [56], or drastically raise (from 0.22-0.47 to 33-38 m²/g), evidencing a surface damaging [67]. Partial exfoliation may be kept in mind to explain huge increase of the SSA. If important enough (at least 5-10 m²/g), this roughening could enhance the fibre-matrix adhesion in composite, by mechanical interlocking [56].

When both roughening and smoothing occur, roughening has been reported to happen before smoothing [54]; the latter one has been attributed to a fibre desizing by decomposition under fluorine of the sizing [73].

Correlate surface porous structure of fibrous materials and properties is still an important but difficult issue. As a matter of fact, SSA of carbon fibres is effected by plenty of factors like their average length and degree of packing density but there is a lack of data. In this section, only the available data are discussed.

4.3 Wettability properties

One of the remarkable properties of the (oxy)fluorination of carbon fibres is to confer them a hydrophobic or hydrophilic behaviour, depending on the chosen experimental conditions and the nature of formed C-F bond. Such modifications of the surface energy can be useful to tailor (oxy)fluorinated carbon fibres as reinforcements in polymers or fluoropolymers.

The wettability of carbon fibres with several liquids seems to be enhanced under mild (oxy)fluorination conditions. This behaviour has been reported in several studies with water [3,58,64–66,113], glycerol [109] or fluoropolymers [72]. This enhanced wettability has been linked with a drastic increasing of the polar component of the surface energy [58,64–66], leading to an increase of the total surface energy, despite a slight decrease of the dispersive component.

The increase of the polar component has been attributed to the formation of C-O hydrophilic bonds and C-F semi-covalent bonds [64–66], which can be evidenced in Figure 4. On the other hand, the decrease of the dispersive component could be explained by the disappearance of the graphitic character induced by fluorination [58]. As previously discussed, some (oxy)fluorination parameters were mild enough to induce hydrophilicity, as reported in the Table 8, rather than hydrophobicity as expected due to the presence of F atoms.

Table 8: Selection of experimental conditions leading to hydrophilicity enhancement

Fluorination method	Temperature (°C)	Pressure (kPa)	Duration	Gas	Source (experiment reported as)
Direct	25 - 110	130 - 2600	1 - 60 h	F ₂ or ClF ₃	n°16, 17, 19 in Table 6
Direct	25	1.3	3 - 20 min	F ₂	[113]
Direct	RT	5	30 min	F ₂ /O ₂ (0.5 O ₂ mole fraction)	[65]
Direct	RT	5	5 - 10 min	F ₂ /O ₂ (0.5 O ₂ mole fraction)	[66]
Direct	25 - 100	200	10 min	F ₂ /O ₂ (50%/50%)	[3]
Direct	RT	5	30 min	F ₂ /O ₂ (0.5 O ₂ mole fraction)	[64]

On the other hand, as expected, an increased hydrophobicity of the carbon fibres can be caused by fluorination. This enhanced hydrophobicity notably leads to a decreased wettability, higher contact angles (θ) and a decrease of the surface energy. Two possibilities can be considered: the treatment can either directly confer a hydrophobic behaviour to the carbon fibre [54,56,61,67,114], or can firstly confer hydrophilic properties such as seen previously, and then render the fibre more hydrophobic when a parameter is modified, e.g. temperature [3], fluorine content [58], treatment duration and pressure [113], or the gas mixture composition [54,64,65].

In the first case, this behaviour can be explained by high F/C ratios [67], by the absence of hydrophilic ionic C-F bonds [67] and by the uncovering of the carbon fibres by sizing degradation [61]. The experimental conditions leading to this immediate hydrophobicity increase are reported in Table 9.

Table 9: Selection of experimental conditions leading to a hydrophobicity increase

Fluorination method	Temperature (°C)	Pressure (kPa)	Duration	Gas	Source; (experiment reported as)
-	100	101.3	-	F ₂	[114]
Direct	378	101.3 (20 mL/min)	15 - 30 min	N ₂ /F ₂ (90%/10%) (HF < 5% in fluorine gas)	n°1-8 in Table 6
Direct	25	-	180 s	F ₂ /O ₂ /N ₂ (1%/18%/81% - 10%/0%/90%)	[61]
APF	-	101.3 (gas pressure: 230 kPa at 35 L/min)	4 min (continuous and batch)	Ionised CHClF ₂ /N ₂ (1:70)	[56]
APF	-	101.3 (gas pressure: 280	4 min	Ionised CHClF ₂ /N ₂	[54]

- 350 kPa at 30 L/min)	(0.15% of CHClF ₂)
---------------------------	-----------------------------------

In the second case, the decrease of the wettability, while the chosen treatment initially favours hydrophilicity of the fibre, can be explained by several parameter variations:

- The carbon fibre nature may be involved; despite close fluorination treatments, it has been reported than Sigri fibres adopted a hydrophilic behaviour, while Torayca fibres became more hydrophobic. The treatments compared here are C1 and T1 in [58]. It highlights the following fact: a treatment that renders some fibres more wettable can confer a hydrophobic behaviour to other fibres.
- The treatment duration acts too; if short fluorination duration (3 min) has been found to decrease the contact angle with water, longer durations (20 to 120 min) have led to a higher contact angle compared to the short fluorination one: $\theta_{3 \text{ min}} < \theta_{20 \text{ min}} < \theta_{120 \text{ min}} < \theta_{\text{non fluorinated}}$ [113].
- An increase in the treatment pressure has been reported as a way to increase the contact angle. Slight increases of the contact angle with water have been reported in [113] when increasing the pressure from 10-30 to 50-100 mmHg, while increasing the pressure of the reactant gas from 5 to 10-80 kPa has led to a huge increase of the contact angle [65], as reported in Table 10. In the same study, the polar component of the surface energy has followed the exact opposite trend while the dispersive component has barely changed, leading the total surface energy to evolve as the polar component.

Table 10: Evolution of the contact angle with water of oxyfluorinated fibres with pressure (values from [65])

Reaction pressure (kPa)	Untreated	5	10	20	40	80
Contact angle with water (°)	113	45	55	85	115	115

- The contact angle with water depends on the treatment temperature. As a matter of fact, oxyfluorinations above 100°C led to an angle increase, while the hydrophilicity was initially increased by this temperature hike [3]. As reported in Table 11, polar ratios $X_p = \gamma_p/\gamma$, where γ is the surface energy and p stands for “polar”, have been found to follow the opposite trend. This evolution could notably be explained by a C-F bond nature modification [3], as previously seen in section 2.

Table 11: Contact angle with water and polar ratio evolution of oxyfluorinated fibres with temperature (values from [3])

Reaction temperature (°C)	Untreated	RT	100	300	400
Advancing contact angle with water (°)	83	80	78	88	90
Polar ratio X_p	0.07	0.22	0.28	0.25	0.24

- The reactant gas play a role on the wettability, as reported in [54], where APF fibres with SF₆/N₂ (0.15% of SF₆) have become more hydrophilic than the untreated fibres

with a higher surface energy, while fluorinated fibres with $\text{CHClF}_2/\text{N}_2$ (0.15% of CHClF_2) have become clearly hydrophobic, with a lower surface energy, as reported in Table 12.

Table 12: Contact angle with water and surface energy of 4 min APF carbon fibres depending on the reactant gas (values from [54])

Reactant gas	Untreated	SF_6/N_2	$\text{CHClF}_2/\text{N}_2$
Contact angle with water ($^\circ$)	73	61	103
Surface energy (mN/m)	44	48	31

Moreover, it has been found in [65] that the oxyfluorination of carbon fibres confers them an optimal hydrophilicity when the F_2/O_2 reactant gas is containing 0.5 mole fraction of oxygen (sample n°3 in Table 7). Modifying this mole fraction has led to an increase of the contact angle with water, and to a decrease of the surface energy. This observation seems coherent with Figure 4, as the sample n°3 is the one with the highest content of semi-ionic C-F bonds, known to be more hydrophilic than covalent ones.

This part, where several studies about wettability of (oxy)fluorinated carbon fibres were reviewed, highlighted the dependence on the chosen experimental conditions and formed C-F bonds; different behaviours exist and the surface energy may be tailored in order to either enhance the hydrophilicity of the fibre while increasing the surface energy, or confer them hydrophobic properties (decrease of the surface energy).

4.4 Surface acidity

The few studies interested in the surface acidity of (oxy)fluorinated carbon fibres point out the same result: (oxy)fluorination tends to acidify their surface. This has been highlighted thanks to three main parameters: the isoelectric point (iep), which focuses on the external surface charges [115] and obtained through the $\zeta = f(\text{pH})$ curve, the pH, and the acid value. The latter value is the mass of potassium hydroxide (KOH) in milligrams that is required to neutralize one gram of a chemical substance.

The acid and pH values have thus been found to evolve respectively from 15 meq.g⁻¹ to 18.2-22.1 meq.g⁻¹ and from 7.02 to 6.95, after oxyfluorination at various temperatures, from RT to 300°C. This slight acidification of the fibres have been attributed to the formation of acid groups, such as carboxyl or carbonyl, created because oxygen acts as an oxidant during the treatment [3,62,63]. This hypothesis is strengthened by FT-IR spectroscopy highlighting the presence of OH and C=O groups at the surface of oxyfluorinated fibres in [3].

The iep evolution has been found to decrease from 3.7 to 2.8 under APF treatment, evidencing a surface acidification which has been attributed to an increase of the number of carboxyl groups after APF, despite a decrease of the relative content of surface oxygen atoms [54]. Similar results have been obtained in [67], where the iep decreased from 3.6 to 3.2 (samples n°5-8 of Table 6). On the other hand, in the same study, the iep has not been lowered for the other tested kind of fibres (samples n°1-3 of Table 6), except for the heavier fluorination treatment (sample n°4 of Table 6). In both cases, the scattering of the ζ_{plateau} values has been assigned to the variation of the amount of -COOH groups, and eventually from a high desorption of F⁻ from the fibre bulk for severely fluorinated fibres.

5 Structural and bulk properties induced by fluorination

In order to know how the (oxy)fluorination affects the structure of the fibres, several analyses were carried out, such as X-Ray Diffraction (XRD), Raman spectroscopy, and Scanning Electron Microscopy (SEM) or simply by measuring the fibre diameter. These analyses allow the extension of (oxy)fluorination of the fibre to be evidenced, i.e. either a surface grafting of heteroatoms or diffusion into the bulk.

5.1 Structural properties

5.1.1 Fluorinated layer depth

The depth of fluorinated layer can be estimated by considering the fibre as a two-phase material, one phase being the external perfluorinated layer, the other one being the internal slightly-fluorinated layer. It has been established that the fluorine repartition in the carbon material can be determined by calculating the ratio $[F/C]_{XPS}/[F/C]_{EA}$, where $[F/C]_{XPS}$ and $[F/C]_{EA}$ are the surface and whole fibre composition, respectively [116].

Three hypotheses are necessary to estimate the fluorinated layer depth:

- The external layer is homogeneously fluorinated, meaning that the XPS ratios characterise the whole layer. The fluorinated layer depth is d_{FL} .
- The fibre bulk is not fluorinated, meaning that all the fluorine detected in EA comes from the external layer.
- The fluorination is homogeneous along the fibre longitudinal axis, which allows to consider only the fibre cross section.

D and S respectively stand for diameter and section, and the subscripts WF, NFB, and FL respectively stand for “whole fibre”, “non-fluorinated bulk”, and “fluorinated layer”. The fluorine repartition in the fibre section can then be written as follows:

$$[F/C]_{EA}S_{WF} = [F/C]_{XPS}S_{FL}$$

This equation can be developed as:

$$S_{FL} = \frac{\pi(D_{WF}^2 - D_{NFB}^2)}{4} = \frac{\pi D_{WF}^2}{4} \frac{[F/C]_{EA}}{[F/C]_{XPS}}$$

And can be rewritten as:

$$D_{NFB}^2 = D_{WF}^2 \left(1 - \frac{[F/C]_{EA}}{[F/C]_{XPS}} \right)$$

Meaning that:

$$d_{FL} = D_{WF} - D_{NFB} = D_{WF} \left(1 - \sqrt{1 - \frac{[F/C]_{EA}}{[F/C]_{XPS}}} \right)$$

Using the latter equation, the fluorinated layer depths of carbon fibres from various studies are given in Figure 6, using the data from these studies, whose experimental conditions are given in Table 6 (samples n°1-8, n°16-21, and n°25-28). The 5 last samples of Figure 6 come from [62], where the fibres have been (oxy)fluorinated with pure F₂ (referred as CF) or a 50/50% vol. F₂:O₂ mixture (referred as CFO) for 10 minutes at various temperatures (RT, 100°C, 300°C, 400°C), with a F₂ pressure set at 0.2 MPa. Several factors seem to influence d_{FL} :

- The latter one appears to increase with the fluorination time, as evidenced by T300-T700 samples: the only difference between T300B, T300C, T300D and T300E is their increasing fluorination time, and so does d_{FL} . The same conclusion can be made for T700 fibres.
- The fluorinating gas mixture is also determining, as highlighted by oxyfluorinated samples, which exhibit deeper fluorinated layers than fluorinated samples: CFO-RT, CFO-20 and CFO-125 have respectively d_{FL} of 0.39, 0.37, and 0.28 μm , against only 0.14, 0.12 and 0.09 μm for CF-RT, CF-20 and CF-125. This depth increase could notably be explained by the fluorination intercalation enhancement allowed by the presence of a Lewis acid (O_2 here), as already explained in section 2. It has however been shown through XRD analyses in [3,65,66] that oxyfluorination globally takes place at the fibre surface, meaning that the calculated depths in this review could be overestimated.
- Other fluorinating gas mixtures, such as 10/90% vol. $\text{HF}:\text{F}_2$ (C3) and ClF_3 (C4), resulted in deeper fluorinated layers when compared to pure fluorine. It should however be noted that C4 fibres have been fluorinated during 60 h, which is much longer than C1 or C2 fibres. Catalytic effect of gaseous HF and MF_n species are well known for graphitized samples [99,103].
- Temperature seems to have an influence on d_{FL} , as shown by the depths of CFO-RT, CFO-100, CFO-300 and CFO-400 fibres, their only difference being their oxyfluorination temperature: there is a gap between fibres fluorinated under and above 300°C. High temperatures could then possibly increase the fluorinated layer depth. This hypothesis is strengthened by the depth similarity of CF-20 and CF-125, 0.12 against 0.09 μm : temperature did not seem to be a depth increaser for these fluorinations under 300°C.

Figure 6: Fluorinated layer depth depending on the sample

It should be noted that the emitted hypotheses probably lead to an overestimation of the fluorine content into the fluorinated layer, as it has been assumed to be the $[F/C]_{XPS}$ one in the whole layer, with all the fluorine of $[F/C]_{EA}$ coming from this layer. In reality, the layer

containing fluorine is probably deeper, with a maximal fluorine concentration $[F/C]_{XPS}$ only at its extreme surface, and a decreasing concentration of fluorine while progressing in the fibre bulk, to finally end and let some graphitic carbon non-fluorinated. The two discussed structures are presented in Figure 7.

Figure 7: Fluorinated carbon fibre structure, (a) according to the previous hypotheses, (b) most probable structure

5.1.2 Raman observations

Carbonaceous materials exhibit two main peaks during Raman analysis. The first one (G-band), around 1580 cm^{-1} , is assigned to the graphitic structure of carbon, while the second one (D-band), around 1350 cm^{-1} , is attributed to disordered finite-size microcrystalline carbon [117]. The ratio of their intensities, I_D/I_G , highlights the amount of defective and crystalline mode in the carbon fibre sample.

Some studies have observed a decrease of I_D/I_G ratio under APF, and have linked it to the carbon sputtering, leading to the removal of surface amorphous carbon by the plasma jet, and to the emergence of graphitic carbon at the fibre surface [54,56]. On the other hand, fluorinations of carbon fibres under high temperatures have led to I_D/I_G increases from 1.06-1.08 to 1.17-1.23, that highlights an increase of the fibre disorder during fluorination [67].

To guarantee a specific analysis of the fluorinated phase, the detection depth of Raman laser should not be greater than the depth of the fluorinated layer, otherwise non-fluorinated graphitic carbon would also be analysed. The penetration depth d_p of Raman laser is known as $d_p = 2/2.3\alpha(\lambda)$, with α the photoabsorption coefficient of the penetrated material [118], and λ the Raman laser wavelength. The evolution of α depending on λ for graphite is given in [119] and allows to gather in Table 13 depth penetrations of Raman laser depending on its wavelength for the articles studied in this section (5.1.2).

Table 13: Depth penetrations of Raman lasers in graphitic materials depending on their wavelengths

Reference	Raman wavelength λ (nm)	Photoabsorption coefficient α (μm^{-1}) ³	Depth penetration d_p (μm)
[67]	532	5.5-7.5	0.18-0.23
[54,56]	633-634	5.0-6.5	0.15-0.21

It can be seen in Table 13 that if the Raman laser penetration depth is 0.18-0.23 μm for the fluorinated fibres in [67], the fluorinated layer depths are 0.10-0.38 μm (T300 and T700 fibres), meaning that for some fluorinated fibres, the Raman analysis also includes graphitic non-fluorinated carbon, according to these calculations. However, as mentioned in 5.1.1, the fluorinated layer real depth may be superior to the calculated values.

5.1.3 X-Ray Diffraction evolutions

XRD diagrams in various works [3,58,65,66,73] about (oxy)fluorinations under mild conditions, reported in Table 1, were barely changed, evidencing that (oxy)fluorination was only taking place at the fibre surface because of the rigidity of the graphitic lattice, which is able to resist to intercalation or bulk fluorination under these conditions.

However, it has been highlighted by XRD that depending on the treatment severity, fluorination could also take place in the bulk of the fibre. Indeed, increasing the treatment duration and pressure (samples n°22-24 in Table 6) has led to a broadening of the 002 peak of the graphitic phase, that indicates the diffusion of fluorine in the bulk of the fibres and a disorder increase, while the slightly fluorinated fibres had the same XRD pattern than the non-fluorinated ones, meaning that fluorine was rather involved in covalent C-F bonding with unsaturated carbon atom defects present at the surface.

The influence of treatment duration on diffractograms has also been reported in [67], where increasing the fluorination time has led to two interesting phenomena: firstly, a shift of the 002 peak to higher 2θ angles, indicating a bulk fluorination of the fibres, has been reported (samples n°7-8 of Table 6). Secondly, the emergence of two new peaks in the XRD patterns has been observed (samples n°3-4 and n°7-8 of Table 6). The first one, around $10-15^\circ$ associated with an interlayer of 6.5-7.4 nm, has been attributed to the 001 plane and to the formation of a fluorocarbon lattice, while the second one, at 44° , corresponds to the 100/101 lines of the graphitic structure. In this study, contrarily to the previous paragraph, a narrowing of the 002 peak, indicating an increase of the crystallite size L_C , has been observed when the fluorination duration increases [67]. This evidences that the fluorination focused on the less ordered graphitic phases keeping the zones with higher crystallinity unchanged with their high L_C , as already reported in [95].

Another study, using XRD patterns to follow fluorine intercalation into carbon fibres, has highlighted that the use of HF in the reactant gaseous mixture leads to a preferential fluorine intercalation than a fluorination using pure fluorine, as reported in section 3. Rather than involved in a covalent C-F bond, fluorine has been preferentially intercalated in the carbonaceous lattice, increasing the disorder and broadening the peaks of the XRD pattern [120]. In accordance with this, changing the reaction atmosphere from pure fluorine to HF/F₂

³ Graphically obtained in [119]

(1:10) mixture has led to the appearance of a XRD peak around 21° in another study, which indicates the formation of stage 3 C_xF [58].

XRD appears as a way to study the way the fluorine interacts with the bulk and the surface of the carbon fibres. Under standard conditions (direct fluorination under pure fluorine at room temperature), fluorine rather bonds to the fibre surface than diffuses into the bulk. Whatever the route, the fluorine interacts with the carbon fibre and allows a wettability evolution, as described in section 4.3.

5.2 Electrical properties

The electrical properties, resistance R , resistivity ρ , or conductivity σ , the latter one being the most studied in literature, evolve with both the fluorination degree and the C-F bonding [66]. As a matter of fact, fluorine intercalation leads to enhanced conductivity, while formation of graphite fluoride tends to decrease conductivity. In both cases, these phenomena are explained by changes in the π -electron system of the graphitic part of carbon fibres [66], which implies major modifications of the fibre bulk properties due to diffusion of fluorine [54].

This assumption has also been reported in [58], where mild fluorinations have led to conductivity increases, while the more severe ones have decreased it: the conductivity of pristine fibres was 530 S.cm^{-1} , while the one of slightly fluorinated fibres was $600\text{-}630 \text{ S.cm}^{-1}$ (samples n°16-17 in Table 6) and the one of strongly fluorinated fibres dropped to 110 S.cm^{-1} . Resistivity and resistance have changed as followed: a weak decrease for slight fluorinations (from $1.9 \text{ }\Omega\text{.cm}$ to $1.6\text{-}1.7 \text{ }\Omega\text{.cm}$ for resistivity and from $7.3 \text{ k}\Omega$ to $6.7\text{-}7.3 \text{ k}\Omega$ for resistance), followed by a significant increase for severe fluorinations (respectively $9.15 \text{ }\Omega\text{.cm}$ and $38 \text{ k}\Omega$).

Similar results have been observed in [67], where the formation of covalent C-F bonds have decreased the conductivity from 640 S.cm^{-1} for pristine fibres to $580\text{-}590 \text{ S.cm}^{-1}$ for fluorinated fibres (samples n°3-4 in Table 6). On the other hand, the intercalation of fluorinated species into the sp^2 structure has increased the conductivity from 900 S.cm^{-1} for pristine fibres to $990\text{-}1020 \text{ S.cm}^{-1}$ for fluorinated fibres (samples n°5 and n°7 in Table 6).

These important conductivity decreases have been explained by the change of the carbon hybridization from sp^2 to sp^3 , which is due to the fluorination of the fibre bulk and to the formation of graphite fluoride already raised in this section [58]. This assumption is strengthened by the fact that high-temperature fluorinated fibres, where fluorine is covalently bonded to sp^3 carbon through $(CF)_n$ and $(C_2F)_n$ phases, are known to be insulators, while low-temperature ($< 100^\circ\text{C}$) fluorinated carbon fibres, where fluorine is intercalated in the graphitic sp^2 lattice as a GIC, exhibit excellent conductivities [96]. More precisely, fibres containing stage-2 GICs, which are produced under F_2 pressures lower than 10 bars, have higher conductivities, while fibres hosting stage-1 GICs, obtained under severe conditions (fluorine pressure of 10 bars) have a much higher resistivity than pristine fibres, around one order of magnitude [120].

To summarize, mild fluorination conditions slightly improve the conductivity while severe conditions lower it drastically.

5.3 Mechanical properties

Regarding the structural changes which may be important in particular fluorination conditions, the mechanical properties of carbon fibres must be investigated as they can change drastically. Several studies have investigated the evolution of the mechanical properties

(tensile strength and Young's modulus) of carbon fibres with (oxy)fluorination. Table 14 computes these studies as well as their tensile test conditions.

Table 14: Tensile test conditions of (oxy)fluorinated carbon fibres in literature

Reference	Gauge length (mm)	Testing rate (mm/min)	Number of measurements
[56] (25-29 in Table 5)	20-50	0.01	25
[61]	10	10	100
[67] (5-8 in Table 6)	25	0.01	20
[59] (25-28 in Table 6)	20	1	20
[60] (22-24 in Table 6)	20	1	20

The data are disparate. On the one hand, sharp increases of ultimate tensile strength (UTS) and Young's modulus have been observed. The UTS and Young's modulus of fibres oxyfluorinated at 125°C have indeed been reported to respectively gain 36% and 32% when compared to the ones of pristine fibres [59]. Similar results have been observed on F₂-HF fluorinated fibres, with increases of 40% and 30% for UTS and Young's modulus respectively [60], and on RT oxyfluorinated fibres, with 12-20% increases of the UTS. These increases were explained by both a diameter decrease of the fluorinated fibres [61], which allows a better alignment of the fibre structure [59,60], and by the removal of surface defects by fluorination [59,60].

On the other hand, important decreases of the mechanical properties have been reported. The UTS of carbon fibres fluorinated with BrF₅ for 30 days have been divided by two (from 2.2 GPa to 1.02 GPa) [109], while the one of high temperature fluorinated fibres have decreased by 33%, and their Young's modulus by 20% [67]. Several factors can explain these decreases: severe fluorination results in damages in both the surface and formation of pit holes [67]. Moreover, the diffusion of fluorine into the fibre bulk [67] and the buckling of sp³ C-F layers compared to the sp² graphitic layers, affect the fibre preferred orientation because of an increase of the interplanar spacing and of a decrease of coherence lengths L_a and L_c [121]. The resulting decreases of the mechanical properties do not obligatory disqualify the fluorinated fibre for reinforcement of composite, thanks to the other obtained properties, for instance adhesive [109] or hydrophobic ones.

Another interesting parameter which is generally decreasing with the fibre fluorination is Weibull modulus [56,61], which quantifies the homogeneity of defect dispersion. Its decrease implies that fluorination increases the heterogeneity of defect dispersion, which could lead to early breakings.

It is to note that the mild fluorination treatments, such as APF or fluorination located only on sizing, allow the mechanical properties of the fibres to be maintained [56,73]. In this case, one could think that these fluorinations did not lead to the formation of critical surface flaws nor to a diameter evolution.

In this part, the mechanical properties of (oxy)fluorinated carbon fibres have been reviewed. In accordance with the induced structural changes induced, (oxy)fluorination allows the mechanical properties to be enhanced if the structure is slightly affected. On the contrary, strong (oxy)fluorination treatments result in drastic rearrangement, the mechanical properties are then degraded.

5.4 Potential applications for (oxy)fluorinated materials

(Oxy)fluorinated fibres are almost exclusively used for composite reinforcement. However, another potential application for fluorinated carbonaceous materials is presented here, even if the latter ones are not fibres, in order to give perspectives for the use of these materials.

5.4.1 Composite reinforcement

When performed in adequate conditions, fluorination may lead to an enhancement of the wettability through the tailoring of the surface energies, and the maintaining, or even an improvement, of the mechanical properties of carbon fibres as previously highlighted in this review. One could think that all these changes open the way for interaction between fluorinated carbon fibres and polymers and fluoropolymers in composites.

First, it has been reported that fluorination enhances the adhesion with epoxy resins [113], which are the most used matrices with carbon fibres [122]. The adhesion thus increases from 75 kg/mm² to 105 kg/mm² under the efficient fluorination conditions: a low fluorine pressure is required (< 50 mmHg), as higher pressures tend to decrease the adhesion down to the initial value between non-fluorinated fibres and epoxy resin. This enhanced adhesion for fluorinated fibres has been related to a higher presence of oxygen-containing groups, which improves the bonding with epoxy.

This enhanced compatibility with a polymer matrix is promising and has also been reported with fluoropolymers. As a matter of fact, the contact angle between carbon fibres and four different liquid fluoropolymers has been reported to decrease from 18.5-19.5° to 14.2-16° with an average decrease of 4°, highlighting the fact that fluorinated fibres are more compatible with fluoropolymers than pristine fibres [72]. This compatibility optimisation has been reached with low fluorine content, i.e. surface F/C ratio of 0.1-0.2), while high F/C ratios of 1.5-1.9 resulted in higher contact angles than with untreated fibres.

This adhesion strengthening leads to an increase of the interfacial shear strength (IFSS), a micromechanical value which characterises the quality and the resistance of the fibre/matrix interface, for example by studying the interfacial resistance of a {single fibre + matrix} system [123,124]. Fluorination has been reported to increase IFSS between four fluoropolymers and carbon fibres from 8.2-18.4 MPa to 18.7-28.7 MPa, with an average increase of 11.5 MPa [72]. As for the case of contact angle measurements with fluoropolymers, IFSS is enhanced by mild fluorinations, and decreases when fluorination is too extended. The authors have highlighted that an optimal compatibility is reached for fluoropolymers when the “matrix to fibre” fluorination ratio is 9:1, meaning that the matrix must have a F/C ratio 9 times higher than the fibre one [72].

Moreover, fluorination has also been reported to modify macromechanical values, such as the interlaminar shear strength (ILSS), the critical stress intensity factor K_{IC} , the work of fracture W_f or the specific fracture energy G_{IC} . Mild fluorination, i.e. 10 min at room temperature under pure fluorine, has led to a slight decrease of these values compared to the ones of as-received carbon fibres, while 10 min of oxyfluorination at various temperatures with 50%/50% F₂/O₂ gaseous mixture have increased these values, with an optimal treatment temperature of 100°C [62]. These macromechanical enhancements have notably been attributed to an increase of the fibre/matrix interfacial adhesion, of the fibre surface acidity and of the wettability; the change of the latter one has been related to an increase of surface polarity. The excellent correlation between the ILSS, K_{IC} and the (F_{1S} + O_{1S})/C_{1S} ratio has confirmed the effect of the presence of heteroatoms F and O [62].

Impact properties, such as impact strength, impact energy and ductility index (ratio of the post-peak energy to the energy to peak [125]), have also been reported to be enhanced by the oxyfluorination procedures described just above, especially at a 100°C treatment temperature. This improvement of impact properties for oxyfluorinated fibres can be explained by the increase of hydrogen bonding, which hinders impact failure mechanisms and interrupts the development of crack paths into the composite [63].

To conclude this section about the way (oxy)fluorinated carbon fibres bond with (fluoro)polymers, it can be noted that when the fluorination rate is low and involves the formation of oxygen-containing species, the micromechanical interaction between fibres and matrix is enhanced, as seen through both the IFSS increase and the wettability decrease. The conclusion is similar about the wettability and IFSS of weakly fluorinated carbon fibres with fluoropolymers. Concerning the macromechanical properties (ILSS, critical stress intensity factor K_{IC} , specific fracture energy G_{IC} , work of fracture W_f , impact properties), the values appear to be enhanced with oxyfluorination, which can notably be explained by an increase of the fibre/matrix interfacial adhesion, of the acidity of the fibre surface, of the fibre wettability, and of hydrogen bonding, which is allowed by the surface chemistry of oxyfluorinated fibres.

5.4.2 Gas sensing

In industrial environments, new sensors need to be developed in order to detect toxic gases, e.g. ammonia (NH_3), at rates as low as possible. The example of NH_3 was chosen as ammonia is amongst the most dangerous gases, both for human health and environment [126]. The electrical properties of carbonaceous materials, especially the nanostructured ones [126], change under gas absorption, making them ideal materials for gas sensing applications. Sensors based on CNTs have already allowed the detection of various gases, e. g. NH_3 [127–130] or CH_4 [131,132].

In order to increase the reactivity, selectivity and sensitivity of carbonaceous materials to gases [133], they can undergo treatments. Among processes for gas sensing improvement such as acid treatments [134,135], plasma ones [136,137], functionalisation with polymers [138], decoration with nanoparticles [139,140], etc. [141], fluorination exhibits numerous advantages [142–144]. In particular, it increases the SSA of carbon nanomaterials [145]. First, fluorinated graphite oxide (GO), using a HF solution, has thus been reported to have a gas sensing response 20 times higher than pristine GO with a better reversibility [146]. Secondly, fluorinated graphene (FG) exhibits higher adsorption energies [147], higher sensitivity and better adsorption [148] of NH_3 than the untreated one. FGs have also been reported to detect a wide variety of molecules other than NH_3 [32], such as formaldehyde [149], dopamine [150], heavy metal ions [151] or humidity [152].

This behaviour of fluorinated carbon materials can be explained both by the strength of the hydrogen bonding between fluorine and hydrogen atoms, taking benefits of the electronegativity of F [147], and by the presence of defects in FGs [25]. Fluorine atoms are also known to play a key role in gas adsorption thanks to their p electrons [145], and their ability to change the charge distributions on the functional groups [146], and especially when the fluorination treatment maintains the sp^2 state of carbon atoms surrounding the CF group [143,153]. Moreover, it has been highlighted that NH_3 and NO_2 are adsorbed by fluorine atoms, hydroxyl groups, and carbon atoms close to the functional groups [32].

6 Conclusions

In this review, the C-F bonding in carbon fibres was first investigated, evidencing its versatility, which depends on the fluorination conditions and the presence of dioxygen in the reactive gaseous mixture. The surface fluorine content has also been carefully reviewed through the computation of numerous XPS studies. Using these data, an explanation for the changes of both surface and structural properties with fluorination is proposed. The diversity of both the treatment conditions (composition of the reactive mixture, temperature, pressure, duration) and the type of starting fibres complicates the generalization. Several antagonist phenomena, such as wettability or electrical evolutions, have been then reported. They act both on the mechanical properties of carbon fibres and on the way the treated fibres bond with polymers in composites. This review also highlights the extraordinary diversity of properties that can be obtained on carbon fibres thanks to (oxy)fluorination and gives the key parameters to select the (oxy)fluorination conditions in order to enhance the desired properties for a particular application, e.g. fillers in composites and sensitive materials in ammonia sensing.

Declaration of competing interest
